2213 APPLICATION OF SOIL MECHANICS IN DESIGNING BUILDING FOUNDATIONS.
By A. Casagrande and R. E. Fadum 383
Discussion:
By Jacob Feld 417
Leonard Zeevaert 419
Gregory P. Tschebotarioff 422
Guthlac Wilson 424
W. H. McAlpine 426
Karl Terzaghi 427
D. P. Krynine 435
O. G. Julian 438
A. A. Eremin 443
D. M. Burmister 444
Abraham Woolf 448
Lazarus White 452
George L. Freeman 454
Soil Mechanics Committee of the Los Angeles Section—Trent R. Dames, Chairman, Frederick J. Converse, Sterling S. Green, and Paul Baumann 459
A. Casagrande and R. E. Fadum 463

2214 STRAINS, STRESSES, AND SHEAR IN ENGINEERING PROBLEMS.
By Silas H. Woodard 491
Discussion:
By C. M. Goodrich 501
Maurice P. Van Buren 502
Joseph A. Wise 503
David B. Hall 506
Roberto Contini 509
I. Nelidov 511
Bernard L. Weiner 514
Richard W. Albrecht 517
Duff A. Abrams 520
C. A. P. Turner 529
Mark W. Huggins 533
A. A. Eremin 533
Silas H. Woodard 535

2215 AERATION OF SPILLWAYS.
By G. H. Hickox 537
Discussion:
By Joe W. Johnson 557
J. W. Howe and Claud C. Lomax, Jr. 559
J. C. Stevens 563
G. H. Hickox 565

2216 CONCRETE RESERVOIRS OF THE VERTICAL-BEAM TYPE.
By C. Maxwell Stanley, Jr. 567
Discussion:
By Lewis A. Schmidt, Jr. 577
Victor H. Cochrane 577
R. E. Koon and J. C. Gearhart 580
Gustavo Pérez Guerra 587
C. Maxwell Stanley, Jr. 590

2217 FLOW AROUND BENDS IN STABLE CHANNELS.
By C. A. Mockmore 593
Discussion:
By J. M. Robertson 619
Joe W. Johnson and M. A. Selim 623
I. Nelidov 625
S. M. Woodward, J. W. Howe, and C. J. Posey 626

FOREWORD

A comprehensive Symposium on the conformity of model to prototype behavior has been in the minds of the Executive Committee of the Hydraulics Division for a number of years. The Committee on Hydraulic Research (J. C. Stevens, M. Am. Soc. C. E., Chairman), appointed in April, 1934, has announced this subject as one of its major interests (1),[1] and the present Symposium is the result of the efforts of Subcommittee 2, comprising Clarence E. Bardsley, M. Am. Soc. C. E., and Joseph B. Tiffany, Jr., Jun. Am. Soc. C. E., with E. W. Lane, M. Am. Soc. C. E., as Chairman. Credit should also be given to Paul W. Thompson, Assoc. M. Am. Soc. C. E., and Herbert D. Vogel, M. Am. Soc. C. E. Lieutenant-Colonel Thompson succeeded Colonel Vogel on the committee and was in turn succeeded by Mr. Tiffany.

Two of the papers were first presented at the San Diego, Calif., meeting of the Division in July, 1941; one was presented at the Denver, Colo., meeting of the Division in July, 1940; the remaining papers have not been presented publicly in any form. Some papers on this subject have been published separately and these are included in the Bibliography (2) (3) (24). Each author is outstanding in the art of model experimentation and in the analysis of results, and has had an opportunity to determine how nearly the model tests conformed to the prototype observations.

The objective of this research can be stated as a single question: "Does the prototype act as the model predicted?" It is rather difficult to obtain complete conformity for two or three reasons. For example, working conditions may not even approach the load limit that was used in the model; and the prototype rarely is built precisely in accord with the model. The purpose of the Symposium is to assemble the results of a wide variety of studies in which actual comparisons have been made so that hydraulic engineers may judge the sufficiency of the model as a tool in design.

[A rigorous and careful wartime censorship was necessary when this Symposium was first published (October, 1942). In this final printing it has been possible to restore the identity of many of the objects mentioned. This has been done, in some cases, by inserting an explanatory footnote as necessary. —Ed.]

[1] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography, which appears as the last unit of the Symposium.

HYDRAULIC STRUCTURES

BY JACOB E. WARNOCK,[2] M. AM. SOC. C. E., AND H. G. DEWEY, JR.,[3]
JUN. AM. SOC. C. E.

SYNOPSIS

Some of the general factors involved in making model-prototype comparisons of hydraulic structures are mentioned in this paper. Reasons for desiring comparisons, the types made, the difficulties encountered, and the measurements and instruments required are discussed briefly. Citing two of the comparisons made by the Bureau of Reclamation as examples, an account is given of a small irrigation structure, and of the pressure and discharge tests on the 102-in. river outlets of the Grand Coulee Dam in the State of Washington.

INTRODUCTION

Although great progress was made during the 1932–1942 decade in the use of hydraulic models to aid in the design of hydraulic structures, there has been but little progress in comparing the performance of a model and its prototype. It is of considerable interest and importance to make such a comparison in order to determine the degree with which the model may be relied upon for quantitative results even if the laws of similitude have been rigidly followed. In the field of hydraulic structures this is of particular value when applied to discharge coefficients, water-surface profiles, erosion of river beds, and pressures on boundary surfaces, among others. Of nearly equal importance is the fact that reliable prototype measurements will furnish accurate design data enabling more economical designs in the future.

The reasons why little progress has been made in comparing the hydraulic performance of a model and its prototype may be explained by a lack of interest, particularly after the prototype is in satisfactory operation; a natural reliance on model theory; and the difficulties of making prototype measurements. Fortunately, considerable interest is now being shown for making these comparisons and it is believed that this Symposium not only will assist materially in helping to create more interest but, perhaps, from the exchange of ideas, the difficulties involved in making the comparison will be lessened.

Accordingly, this paper will treat some of the recognized difficulties in procuring prototype measurements, together with the measurements and instruments required. Two types of comparisons between model and prototype will follow, one qualitative and the other quantitative. The former is the easiest and the most frequently made. It consists of describing, for example, the observed performance of some structure for several flows, and then comparing these observations with those made of similar flows in the model. It is recognized that this type of comparison is of particular value only to those most familiar with the structure, is not too convincing to others, and leads the engineer no nearer to actually verifying the quantitative results of the model. Obviously, a quantitative comparison is the most valuable since it not only will permit direct comparison between several quantitative factors of the model and prototype, but it will also begin to establish the degree with which the model can be relied upon. The hydraulic model is reliable to a high degree, because the laws of similitude in themselves are fundamentally sound when used correctly; but it is of importance to obtain concrete evidence and thereby recognize the influence of any digressions made in conducting the model experiments.

FACTORS MAKING COMPARISONS DIFFICULT

Prototype Measurements.—The difficulty of obtaining accurate prototype data is the principal reason why correlation work has been delayed. Although several methods are available for measuring the flow, the difficulty lies not only in actually being able to procure the measurements, but also in being able to obtain data applicable to the particular feature of the prototype for which a comparison is to be made. In these respects the discharge, velocity, and water-surface measurements are the most troublesome.

Ordinarily the discharge passing a structure can be measured at a gaging station downstream. During flood flows, however, it is frequently impossible to obtain an accurate measurement because of a change in river section due to bed movement, or because the peak flow may pass before a complete measurement is recorded. Occasionally a flood will occur at night, whereupon an automatic gage, if installed, must be relied upon or the measurement is lost. On the other hand, it is sometimes necessary to wait many years before a structure operates, and even then a sufficient range of head and discharge may not be obtained. Frequently the discharge passing a structure may be derived from the simultaneous operation of a spillway, outlet works, and power house. In such an event it is usually necessary to wait until the flow is derived from only one source, but by that time the range of measurements desired may have passed. Similarly, if a confluence of streams exists between the structure and gaging station, or if heavy rainfall occurs, a discharge measurement adjusted to be applicable to the structure may be of questionable value.

Perhaps the most trouble is encountered when it is desired to obtain velocity and water-surface measurements, not only for comparison with the model, but also for procuring fundamental data. If the flow travels at slow velocities and is confined in narrow channels, these measurements may be made with a minimum of difficulty. If the flow travels at high velocities, however, the measurements are extremely troublesome, regardless of the size of channel. For example, how would one measure accurately the velocity and water surface of the flow in the spillway section of a dam in a western state or of the dam in question here[3a] where the velocity is in excess of 100 ft per sec, and the water surface is affected by air entrainment? It is impracticable to use current meters or pitot tubes to measure the velocity, or point gages to obtain the water surface.

[3a] Of Shasta Dam in California or of Grand Coulee Dam.

The futility of using pitot tubes was realized at Grand Coulee Dam, more from the trouble of maintaining the equipment than from the magnitude of the quantities to be measured. During construction three streamlined, bronze piers, about 21 in. high, were fastened to bronze base plates at the entrance and on the lip of the spillway bucket. Each bronze pier supports five stainless-steel pitot tubes whose static and dynamic openings are connected within the piers to hydrostatic pressure cells similar to those used for measuring seepage pressures in earth dams. Each cell is connected to an instrument panel in a gallery at a higher elevation by copper tubing extending through the dam. To provide check measurements, a by-pass is formed at each cell and connected by copper tubing to manometers in the gallery. In spite of all the precautions made, many of the copper tubes leading to the gallery became plugged and all attempts to clear them failed. Some of the diaphragms of the pressure cells were ruptured during the attempts to clear them. It is also feared that debris in the tailwater has plugged or coated some of the pitot-tube openings and may have damaged the entire assembly from impact, which may be even more severe since the start of spillway operation in June, 1942. As a result, it is doubtful that any reliable measurements can be taken with this equipment, even though carefully planned and all precautions taken to assure an efficient arrangement. It was realized that the pitot-tube assembly might be inadequate, so the salt-injection method will be attempted making use of electrode plates, which were also installed at intervals down the spillway section of the dam. As yet no suitable methods have been developed to measure the water surface for the high-velocity flow occurring in spillways at high dams or in other open channels.

Difficulties are also encountered when measuring velocities in large outlets under high heads because of the tremendous forces involved, which either necessitate extremely rigid instruments or prohibit the use of instruments entirely. Lack of access also eliminates any measurements, particularly if previous preparations have not been made for installing the necessary equipment during construction.

The success with which other measurements can be made in the field, such as pressures on boundary surfaces, vibrations, and air-demand, depends more on the careful planning of the instruments, the ability to foresee their workability, and their installation, than upon the difficulties of actually being able to obtain the measurements.

Planning and Cost.—Since the success of any verification depends upon the flow measurements made on a model and its prototype, it is compulsory to formulate plans for the comparison during the laboratory experiments and during the design of the structure. Such plans should provide for quantitative model data covering several flows, not just the maximum, and for the installation of piezometers, gages, and special instruments in the prototype design as dictated by the model tests. As a result of careful planning, the unfortunate condition of having prototype data in one range and model data in another will be avoided, even though it might be possible to regulate the prototype tests to conform to similar ones of the model—a condition which rarely exists.

The success of any planning, moreover, depends upon the circumstances under which the laboratory tests are made. Usually tests are performed under considerable strain because of the limited time available after the preliminary design is submitted for testing and before the final design is prepared for construction. Discovery of faults in design during construction also requires model experiments to be made quickly so as not to interfere with the progress of construction. Because of this constant rush, the model data usually do not cover the desired range, thorough checks on the data are not possible, and the adequacy of the prototype measuring equipment may suffer.

If some flow measurements have been made over a period of years at a structure never previously tested by a model, it is of considerable interest to construct a model and secure the data necessary for a comparison. This reversed procedure has been tried at the University of Iowa, at Iowa City, Iowa (see paper by Mr. Soucek in this Symposium), as an academic study, and was used recently at the Bureau of Reclamation, but for the primary purpose of revising hydraulic conditions at an existing structure.

The cost of taking field measurements will be greatly reduced if plans provide for the installation of equipment during construction Once the proper arrangements have been made, the actual cost of making the measurements will be small in comparison with the entire cost of the structure itself. The cost of instrumentation, on the other hand, is relatively high and in many cases prohibits any field measurements.

Properties of the Model.—Not all of the difficulties in making comparisons are attributed to the prototype tests; in fact, most of them must be traced directly to the model experiments, assuming, of course, that the prototype data are reasonably accurate. This is evident since any comparison actually is a check on the model tests, not on the prototype. In open-channel studies a small error is introduced because it is usually impossible to select a scale ratio that will permit rigorous similitude between model and prototype roughness, the model surfaces being too rough. During experiments on different scale models of sluices in the Assuan Dam (4), in Egypt, it was found that models having a surface roughness commonly used today agreed with the prototype discharge within 2%. When the model surfaces were roughened artificially with sand, however, the model discharge decreased 5%. From measurements on five geometrically similar models of spillways, F. Eisner (5) showed that there was a definite variation in the coefficient of discharge with the scale ratio. The relative roughness of the boundary surfaces was believed to be the important factor, the effects of viscosity being almost negligible. Because of the uniform variation between the coefficients of discharge and the relative roughness, Eisner predicted the prototype coefficients reasonably well, in comparison to extrapolating by the Froude number.

A much greater error is introduced in model studies of closed conduits because it is practically always impossible to operate the model at Reynolds numbers as high as those obtained at the prototype. It is important to realize, therefore, that the model friction losses are too large, and that a correction should be made to the model data before estimating any corresponding prototype values. Other errors introduced by such fluid forces as capillarity and elasticity are negligible in the problems usually studied in hydraulic laboratories. In any event it is well to know the requirements for similitude, how to apply them, and their effects on the results.

In regard to the model data, they are usually more accurate than the prototype measurements, since errors in the field are not controlled as easily as they are in the laboratory. In this regard it should be determined if the model and prototype dimensions are geometrically similar, because frequently the field structure may not be constructed in accordance with the dimensions used for the model.

PROTOTYPE FLOW MEASUREMENTS

Since it is necessary to take nearly the same measurements in the field as in the laboratory, instruments should be available for measuring the discharge, pressure on boundary surfaces, water-surface elevations and profiles, velocity, vibration, air-demand, bed movement, and for photography. Keeping in mind the difficulties mentioned in obtaining prototype measurements, several well-known methods will be outlined. Although the instruments used in the laboratory and in the field are basically similar, the prototype equipment must be designed to withstand tremendous forces and be convenient for use. With little precedent to follow, one must rely on good judgment for the design of the instruments and, at the same time, be able to foresee their efficacy.

Discharge.—Open-channel flows can usually be measured by current meters, pitot-tube or pitometer traverses, weirs, Parshall flumes, floats, and the salt-injection method. The particular method used depends on the accuracy required, the size and type of channel, quantity of water, and its velocity. Accordingly, a current meter is used most frequently in rivers, lined channels, and in canals. Smaller quantities in canals are measured with weirs or Parshall flumes. For high-velocity flow in lined channels, the salt-injection method is used unless the discharge measurement can be made at some other place where a more convenient method could be adapted.

Discharges in closed conduits are obtained by pitot-tube traverses, the salt-velocity method, the Gibson method, and by venturi meters when installed in the conduit. These methods are adaptable only if plans have been made for their use, since it has been pointed out that it is often impossible to gain access to many conduits in dams. If access is impossible, the discharge probably could be obtained downstream at a gaging station.

In most of these methods a calibration of the instruments is required, and it is debatable whether the calibration of some of them will be the same at the test site as it is at the place of calibration. Using a rating curve at the prototype which has been established from model tests obviously defeats the purpose of making a comparison.

Pressure.—Piezometers, which are used almost exclusively to obtain pressures on boundary surfaces, should be installed on the prototype in positions similar to those on the model. The installation of piezometers in two of the 102-in. river outlets of the dam[3b] is offered as an example. Piezometers in these outlets have been placed on the vertical and horizontal diameters. Each opening consists of a high-tension bronze plug drilled with a $\frac{1}{4}$-in.

[3b] Grand Coulee Dam.

hole and screwed into the steel plate lining of the conduits, with the orifice end projecting about $\frac{1}{16}$ in. past the interior surface. After this projection had been ground flush with the surface lining, a $\frac{1}{16}$-in. radius was formed in the orifice end and all burrs were removed. A short length of $\frac{1}{8}$-in. standard brass pipe connects each plug to a steel junction box, where a reducing coupling is used to connect each piezometer plug to $\frac{3}{8}$-in. outside diameter by 0.035-in. wall, soft copper tubing. Junction boxes placed opposite each plug are connected by 2-in. galvanized conduit, through which the soft copper tubing is collected, and lead to six headers recessed in an inspection gallery below the outlets. The headers, one placed above the other, are made of 2-in., extra-strong brass pipe, with $\frac{1}{8}$-in. brass air cocks placed in rows along the top of each header to make connection with each piezometer line. Each header is connected to a high-pressure line at one end and to a bleeder pipe at the other end, which, in turn, is connected to a pressure measuring instrument through a by-pass.

A similar method could be used for measuring pressures on concrete surfaces, except the piezometers would be attached to a metal plate set in the concrete. In any event the installation must be made during construction.

To measure the pressures, it is common practice to use water or mercury manometers, and dial gages. Manometers are not always satisfactory because of their fragility, the fluctuations of the mercury columns, and the magnitude of the pressures frequently encountered. Commercial-type dial gages are usually not precise enough. A fluid-pressure scale of the type used for turbine testing proved satisfactory in high-head tests at the two dams.[3c] Pressures as great as 300 lb per sq in. can be recorded within 0.25 lb per sq in. to pressures of 100 lb, and within 0.25% at any pressure greater than 100 lb with this instrument, which is compact and of simple construction. When reading piezometer pressures, the pressure is transmitted to a copper tube grid mounted in gimbals in a weighing beam in the base of the instrument. The weighing piston, which is lapped fit in the cylinder, is restrained from being forced upward. The resulting downward reaction on the weighing cylinder is transmitted, therefore, to the lower weighing beam, and measured on an upper scale beam mounted above the base. The weighing piston is rotated by a small electric motor while readings are being made to avoid static friction with the walls of the cylinder.

Pressure cells used in combination with a group of piezometers and an oscillograph may be used, but the cost of such equipment is prohibitive in many cases unless it is available from previous experiments. This method has one advantage in that a continuous record of the pressure fluctuations is recorded on the film or sensitized paper in the oscillograph.

In making any pressure measurements either on the model or prototype, the care with which the piezometer openings are installed cannot be overemphasized. Any burr will affect the reading seriously, and excessive surface roughness either upstream or downstream from the piezometer opening will influence the measurements. It is essential to have a high-pressure water line for flushing the piezometer lines clear of air bubbles, and the tubing from the piezometer to the measuring instrument should be alined, if possible, to eliminate any bends or sags that might trap air.

[3c] Boulder Dam (Arizona-Nevada) and Grand Coulee.

Water Surface.—Although these measurements are not as important as the discharge and pressure, nevertheless a check is desirable on such design assumptions as freeboard and roughness coefficients. In connection with the work of the Society's Special Committee on Hydraulic Research, the problem of air entrainment in high-velocity flow requires, in part, a measurement of the water surface in open channels at field structures. In comparison to the low-velocity flow in models where the water surfaces are relatively smooth and well-defined, there is actually no definite water surface for the high-velocity flow at field structures, but only a mass of spray and aerated water. Efforts to point-gage such a water surface in a narrow wasteway in the Yakima project, Washington, were successful in a measure, but only an "average" water surface was actually obtained.

Although point gages may be useful for measuring water surfaces in narrow channels, it might be more feasible at wide channels to use a system of cables to manipulate a heavy target, which could be located by transits. A profile of the water surface could also be obtained by suspending a plumb bob from the training walls, or from a grid painted on the training walls; but such measurements would be affected by the wall friction.

For measuring water-surface elevations in a reservoir, use has been made of the familiar staff gage and of several commercial instruments. Those based on the principle of a long air column transmitting the pressure should be avoided because of the effect of temperature change on the air column, and because of possible air leaks in the tubing.

Velocity.—The methods available are directly associated with discharge measurements, so use is made of current meters, pitot tubes, salt-injection method, and floats. Although somewhat unsuccessful at Grand Coulee Dam, the installation of pitot tubes, as discussed herein, may prove successful under different circumstances. The accuracy required for model-prototype comparisons eliminates the use of surface and subsurface floats.

Vibration.—It is frequently desirable to measure the vibrations occurring at a prototype structure, not necessarily to compare with the model to establish a relation between the two, but more to ascertain what effect the vibrations may have on the structure itself. The flutter of nappes discharging over the lips of drum gates on the crest of movable weirs or dams is one example of such vibration (6). The discharge at large valves and regulating gates also is frequently accompanied by vibrations. Accelerometers and pressure cells were used with an oscillograph to measure vibrations due to fluttering nappes at a dam in another western state.[3d] The instruments were designed on the principle that a change of resistance occurs with a change in pressure on a pile of carbon disks. The accelerometers measured the accelerations in three directions in the dam, and the pressure cells were used to measure the amplitude and frequency of the inducing forces exerted on the dam by the flutter of the nappes spilling over the lip of drum gates. The instruments were calibrated by noting the deflections produced on the moving elements of the oscillograph under

various conditions created on a shaking table. Less complicated instruments, such as vibrating reeds, which give only the frequency, have been used elsewhere, the amplitude being determined by magnifying the vibration and using an oscillograph.

Air-Demand.—It is often necessary and desirable to measure the quantity of air required on a prototype to relieve sub-atmospheric pressures under nappes, in conduits downstream from needle valves and regulating gates, and in regulating gates and valves themselves. It is a difficult problem to determine the size of air ducts required on the prototype by model tests, because of the uncertainty of the similitude involved; thus any check on the prototype will aid considerably in establishing the transference relations. To measure air quantities on the prototype (and in the model) an anemometer, orifice plate, or pitot tube could be installed in the air ducts. Although not entirely suitable for prototype measurements because of the large quantities involved, a rotameter may be used for model tests.

Bed Movement.—The scour to river channels downstream from dams and spillways is obtained by surveys or by soundings. These measurements, however, can be used only for a qualitative comparison.

Photography.—Still and motion pictures of all flow conditions observed both in laboratory and field work are invaluable for purposes of comparison. Frequently a startling similarity is seen between a model and prototype photograph of some flow phenomenon. For still pictures, the photographic equipment should include at least a standard view camera and a miniature camera, both with fast lens. The motion-picture camera should be equipped for slow-motion. The higher the number of frames per second, the better, because many prototype flows cannot be studied unless considerably slowed down in the motion pictures. Telephoto lens attachments are considered essential for both the still and motion-picture cameras.

EXAMPLES OF QUALITATIVE COMPARISONS

Irrigation Structures.—Such relatively small irrigation structures as diversion dams, check drops, wasteways, and turnouts offer opportunities for making model-prototype comparisons because of their continuous operation at various discharges during an irrigation season. The primary concern at these structures is to prevent scouring of the canal downstream by using a hydraulic-jump stilling basin wherever possible. Consequently, it is sufficient to make only a qualitative comparison of any erosion that occurs. Most of the small irrigation structures in use today are based on designs developed over a period of years, so that model studies have not been utilized except for revising some existing structure of inadequate design. Such a condition required a laboratory investigation of Check Drop 4 in the Sunnyside Main Canal, Yakima project, Washington.

The Prototype.—Because of a gradual growth in irrigation, the Main Canal had to be increased in capacity. To maintain a proper gradient in the canal, twenty-three check drops were installed at intervals of about one and one-half miles. These drop structures, which were built during the period 1907–1916, were similar in design, but decreasing in size downstream as the discharge in the canal became less due to deliveries. Each structure consists of a rectangular concrete basin divided into bays by concrete piers which are surmounted by steel brackets. By placing flashboards between each pair of brackets, the depth of flow between successive drops can be regulated. Wing walls at each end of the concrete basin extend into the canal banks at right angles. The drop in water surface at these structures varies from 30 in. for the maximum to 7¼ in. for the minimum, with a maximum discharge of 1,300 cu ft per sec at the first drop gradually decreasing to 520 cu ft per sec at the last one.

Not many irrigation seasons had passed before excessive scouring developed in the canal immediately downstream from the drops, particularly at the larger ones. All attempts to check the erosion failed, until finally the width of the canal below the drops was increased as much as 50% in some cases. In 1938 the problem of eliminating this scour was assigned to the hydraulic laboratory of the Bureau of Reclamation, Denver, Colo.

Model Tests.—Since the drops were similar in design, Check Drop 4 was selected for study, and a 1 : 15 scale model was constructed. The initial tests in the laboratory demonstrated that the model would reproduce the flow conditions and scour existing in the field (Figs. 1(*a*) and 1(*b*)). Further analysis disclosed that, because of the small drop in water surface, standing waves developed instead of a more efficient energy dissipator, such as the hydraulic jump. As a result, high surface velocities proceeded downstream in the center of the canal, thereby producing large return eddies along the canal banks which eroded them severely.

A satisfactory solution to this problem was not readily apparent, for not until many designs had been tested was a solution found which would eliminate the unfavorable conditions completely. This solution consisted of adding curved training walls in the entrance to the drop, extending vertical walls and a concrete floor downstream to form a stilling pool, and placing a deflector between these walls directly above the concrete basin to force the flow under the tailwater. These revisions created a more uniform flow distribution through the structure, and provided energy dissipation sufficient to eliminate the high surface velocities which had caused side eddies to scour the canal banks.

Comparison.—After the prototype had been revised, observations of its performance showed that it was acting in a manner similar to that predicted by the model tests. Figs. 1(*c*) and 1(*d*) show the revised design of the model and prototype. The collection of debris at the prototype structure is evidence of roller action in the stilling pool. This is indicative of energy dissipation throughout the entire depth, instead of only on the surface as noticed in Figs. 1(*a*) and 1(*b*).

During the laboratory studies a similar collection of debris was noticed, but it was given little consideration since it interfered with photographing the action of the model. In the field, however, it has been of considerable value in clearing the canal of large quantities of debris, conveniently removed at the drop structure. Three miles downstream at Drop 6 (which was also revised), there is little trash remaining in the canal.

The results of this comparison are of considerable satisfaction to those familiar with the problem, but as previously mentioned such a correlation is more convincing to those directly concerned. Nevertheless, this study is offered as convincing proof that model tests are an excellent tool for the hydraulic engineer, and that they can be relied upon to a high degree.

Examples of Quantitative Comparisons

The Prototype.—Sixty 102-in. outlets were provided in three tiers of 20 each at the dam[3b] to release a total discharge of 225,000 cu ft per sec (Fig. 2). Each outlet has a bellmouth entrance followed by a length of straight conduit, which terminates in an elbow and cone at the downstream face of the dam. Each outlet is closed by a service gate and an emergency gate, partial gate openings never being used with ring-seal or paradox gates. Except for a part of the lower tier, each outlet has a steel-plate lining. The three tiers of outlets at El. 1136.67, El. 1036.67, and El. 935.76 are designated as the upper, intermediate, and lower outlets, respectively. Since the outlets occur in pairs in each tier, 15 ft on centers, further designation is given by east (E) and west (W), and by the block number in which they occur. Fig. 3, for example, shows upper outlet 63W discharging down the face of the dam.

Fig. 2.—Spillway Section, Grand Coulee Dam

During the design of the outlets, plans were formulated for installing piezometers in one intermediate outlet, 51E, and one upper outlet, 51E, 100 ft immediately above. Piezometers were not placed in the lower outlets because they were not completely steel-lined and because detailed model studies were not made of them. In locations similar to those in the model, a series of eleven piezometers have been placed in the bellmouth entrances along both the invert and crown (vertical center line), and on the sides (horizontal center line). Similarly, the horizontal part of the two conduits contains twelve piezometer rings in the intermediate outlet, and ten in the upper outlet; both have ten rings in the elbow and cone. The installation methods have been described and the vertical section of an intermediate outlet shown in Fig. 4 indicates the distribution of piezometers.

[3b] Grand Coulee.

Model Tests.—A résumé of the 1 : 17 scale model tests on the outlets of the dam[3b] has been given in another paper (7). The tests were concerned with the bellmouth entrance, the profile of the outlets, the elbow and cone, and the deflectors placed in the spillway immediately above the exit of the upper and intermediate outlets, which can be seen in Figs. 3 and 4(*a*). Measurements on the model were concerned primarily with the pressures on the boundary surfaces, measured with water and mercury manometers, and the discharge for several heads, obtained from weir measurements.

Only the model data from the intermediate outlet tests will be used for comparing with the prototype. Some tests were made in the laboratory on the lower outlets, but no piezometers were installed in the prototype, and since the upper outlets are quite similar to those in the intermediate tier, additional tests were not required.

Prototype Tests.—Twenty-three tests were made on the intermediate and eight on the upper outlets. Heads above the exit ranged from 28 ft to 234 ft

FIG. 3.—UPPER OUTLET 63W; GRAND COULEE DAM, DISCHARGE 2,400 CU FT PER SEC

for the intermediate outlet, and from 33 ft to 133 ft for the upper outlet. In addition to measuring pressures with the fluid pressure scale, the reservoir elevation, water temperature, tailwater elevation, discharge, and the number of outlets open in each tier were recorded. To make comparisons with the model of the intermediate outlet, it was possible to use only those tests in which the adjacent outlet, 51W, and the upper outlet, 51E, were closed. This not only conformed with the laboratory arrangement, but it also eliminated from consideration any secondary effects on the pressures. These effects were discovered first during a separate model investigation of the bellmouth, and later during the prototype tests when it was noticed that pressures in the bellmouth were slightly lowered when the adjacent outlet 51W was operating, while pressures in the elbow and cone were raised when the upper outlet 51E was operating.

FIG. 4.—DIMENSIONS AND DETAILS OF AN INTERMEDIATE OUTLET, GRAND COULEE DAM

Notation.—The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference under "Bibliography and Notation" at the end of the Symposium.

Model-Prototype Pressure Characteristics.—The first comparison given in Fig. 5 is intended to show the characteristics of the hydraulic gradient. Because the field tests could not always be made when the reservoir reached a corresponding elevation, the model and prototype heads shown are not comparable. Upon first consideration it would seem desirable for the heads to agree, but even if they did, an agreement between the model and prototype pressures would be lacking. The reason for this is evident from Fig. 6, where it may be seen that the model tests were made at much lower Reynolds numbers (R); hence the friction losses

$$f = \frac{h_f}{\frac{L}{D}\,\frac{V^2}{2\,g}} \qquad \text{(1)}$$

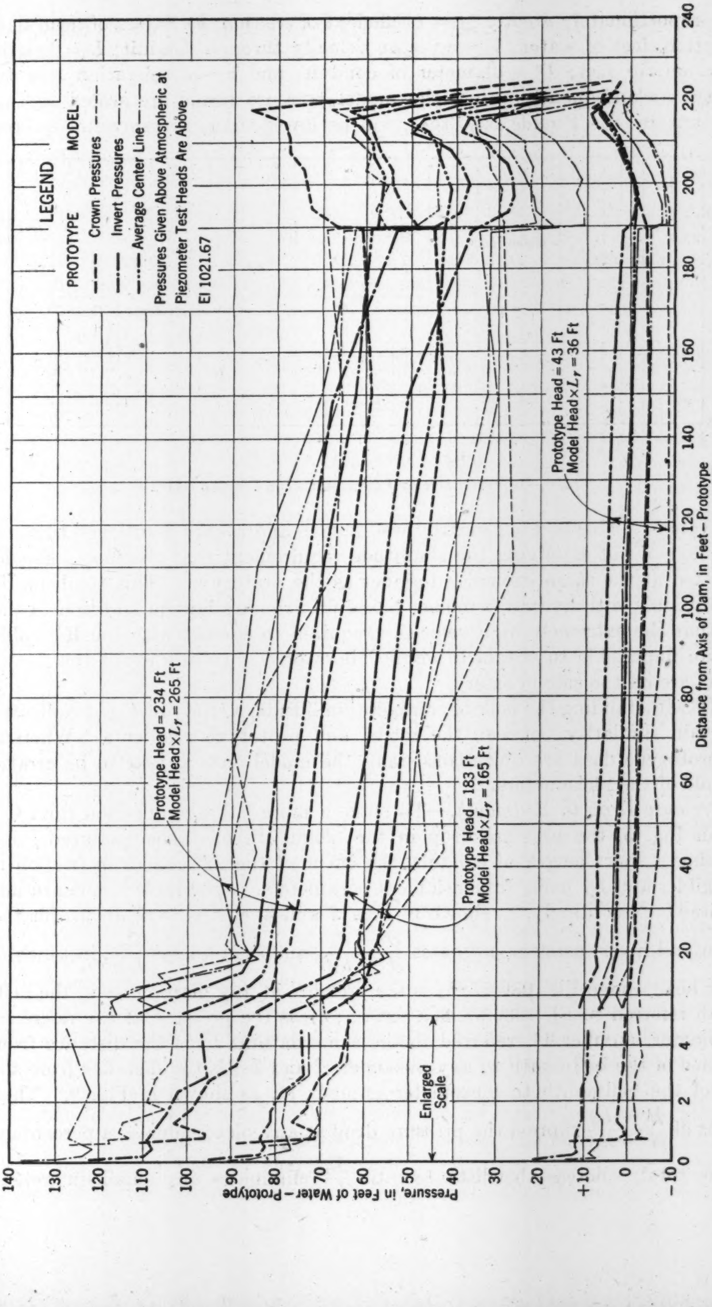

Fig. 5.—Pressure Characteristics, Model and Prototype, Grand Coulee Dam

were proportionately greater (f = coefficient of friction; h_f = loss of head due to friction, feet of water; V = average velocity through conduit; L = length of section, in feet; D = diameter of conduit; and g = acceleration due to gravity). Consequently, when the model pressure heads are scaled to the prototype by the Froude law, they will be lower than corresponding prototype values. This fact is generally well-known and is only mentioned to show the effect of not satisfying the similitude requirement that the model should be tested at the same Reynolds number as the prototype. This condition is incompatible with hydraulic models based on Froude's law, in addition to the fact that the extremely high velocities required to comply with the Reynolds law are impossible to obtain in many laboratories. In any event the model results are on the side of safety.

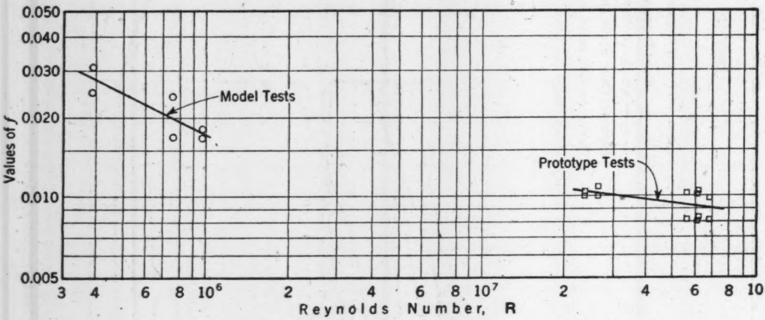

FIG. 6.—COEFFICIENTS OF FRICTION, GRAND COULEE DAM

Notwithstanding the lack of complete similitude, a study of Fig. 5 indicates a certain similarity between the model and prototype gradients. Whereas the prototype data are quite consistent, the model data appear to be erratic at some of the piezometers.

Pressure Drop in Bellmouth.—To make a more valid comparison than the one in Fig. 5, the pressure drop in the bellmouth has been analyzed. By choosing a short length of conduit, the effect of the differences in friction is negligible, and by using dimensionless parameters, comparable heads are not required. Accordingly, as shown in Figs. 7 and 8, curves were drawn for the crown and invert using as ordinates $\frac{H - h_x}{H - h_{11}}$, and as abscissas $\frac{L_x}{L_{11}}$, in which H is the head above El. 1036.67; h_x is the pressure at any piezometer in the bellmouth referred to El. 1036.67 as a datum; h_{11} is the pressure at the reference piezometer, number 11, referred to the same datum; L_x is the distance from the face of the bellmouth to any piezometer; and L_{11} is the distance from the face of the bellmouth to piezometer number 11, as shown in Fig. 9. Then values of $\frac{H - h_x}{H - h_{11}}$ express the pressure drop at any piezometer as a percentage of the total, whereas the distance ratio $\frac{L_x}{L_{11}}$ eliminates any small differences between the location of piezometers in the model or prototype. Two of the prototype tests were omitted from the diagrams so as not to confuse them with more superimposition of the points, but all of the model values are included. The actual pressures at the piezometers in the bellmouth were all positive (above atmospheric) except for low heads, and these did not exceed a vacuum of 10 ft of water.

The prototype curves illustrate that the percentage pressure drop is practically constant at nearly all the piezometers regardless of the head. This is not true for the model tests, even though the average values of the model are within approximately 5% of the prototype. Reasons for the dispersion of the model data may be explained by experimental error, different approach conditions, and unstable flow in the model at lower Reynolds numbers, although above critical Reynolds numbers.

Experimental errors are probably due to the installation of the model piezometers, even though great care was taken to install them properly. Nevertheless, any minute obstructions on the boundary surfaces and in the piezometer openings have serious effects. The laboratory experiments, moreover, were made under considerable duress to enable the design to keep ahead of construction in the field. Consequently, the customary close checks on the data could not be made as complete as they would have been under a more normal procedure. The different approach conditions refer to the absence in the laboratory of a trashrack upstream from the bellmouth. However, it was observed from separate tests on the bellmouth that the trashrack effects were negligible.

Evidently the differences in friction play a small part even though a comparison is confined to the bellmouth alone. No estimate can be made readily of the relative roughness of either the model or prototype surfaces, but, since the type of surface in each is nearly the same, the relative roughness of the model would be greater. Consequently at lower Reynolds numbers, the resistance factor for the model will vary considerably more within its range of tests. It can be assumed further that the model tests were for rough flow, whereas the prototype tests were more nearly smooth flow. Finally, it might be added that a transition from a laminar sublayer to a turbulent sublayer will develop less rapidly in the model, thus influencing the velocity distribution and pressures. It is reasonable to assume, therefore, that the model flow is not sufficiently stable to give the consistent data obtained for the prototype. Accordingly, it is believed that the laboratory tests should have been made at greater velocities (higher Reynolds numbers), disregarding heads based on the scale ratio of the model. Had this been done, the model data as analyzed in Figs. 7 and 8 would have been more consistent and would have approached the prototype values more closely, although 5% is certainly good agreement for the average curves.

Pressure Drop in Elbow and Cone.—Dimensionless curves have been drawn in Figs. 10 and 11 to show the pressure drop in the elbow and cone in a manner similar to that described for the bellmouth comparison. To eliminate the differences in friction up to the elbow, the pressure drop has been expressed as

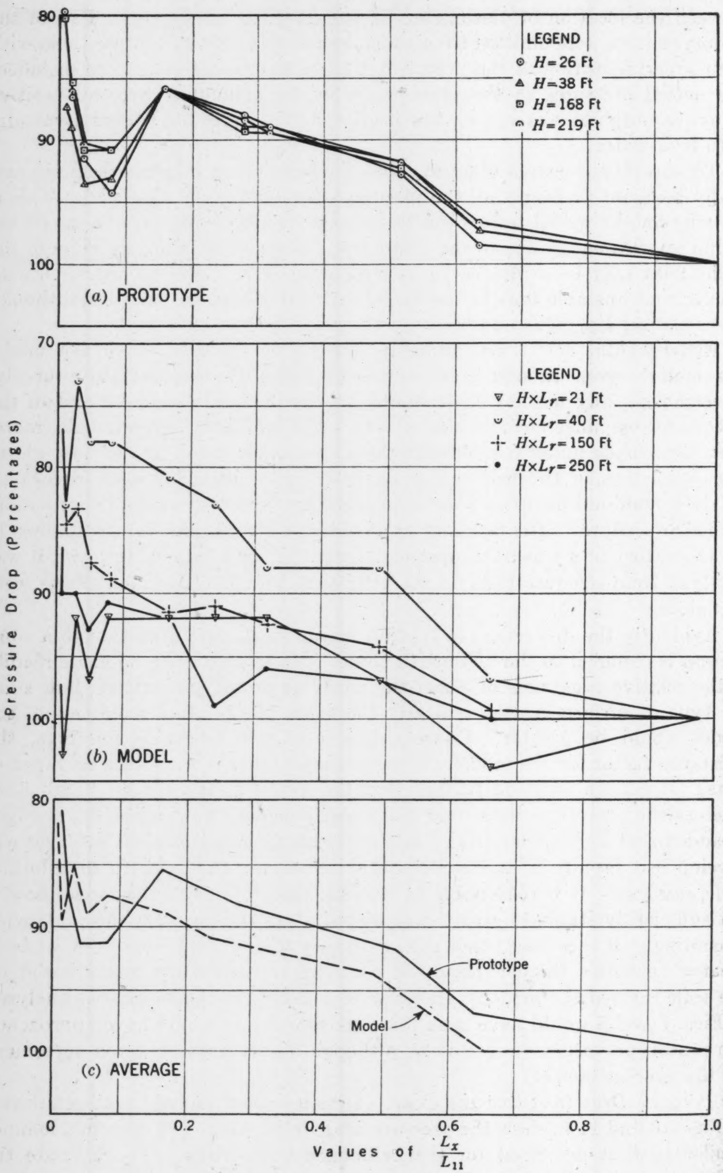

FIG. 7.—COMPARISON OF PRESSURE DROPS ON CROWN OF BELLMOUTH

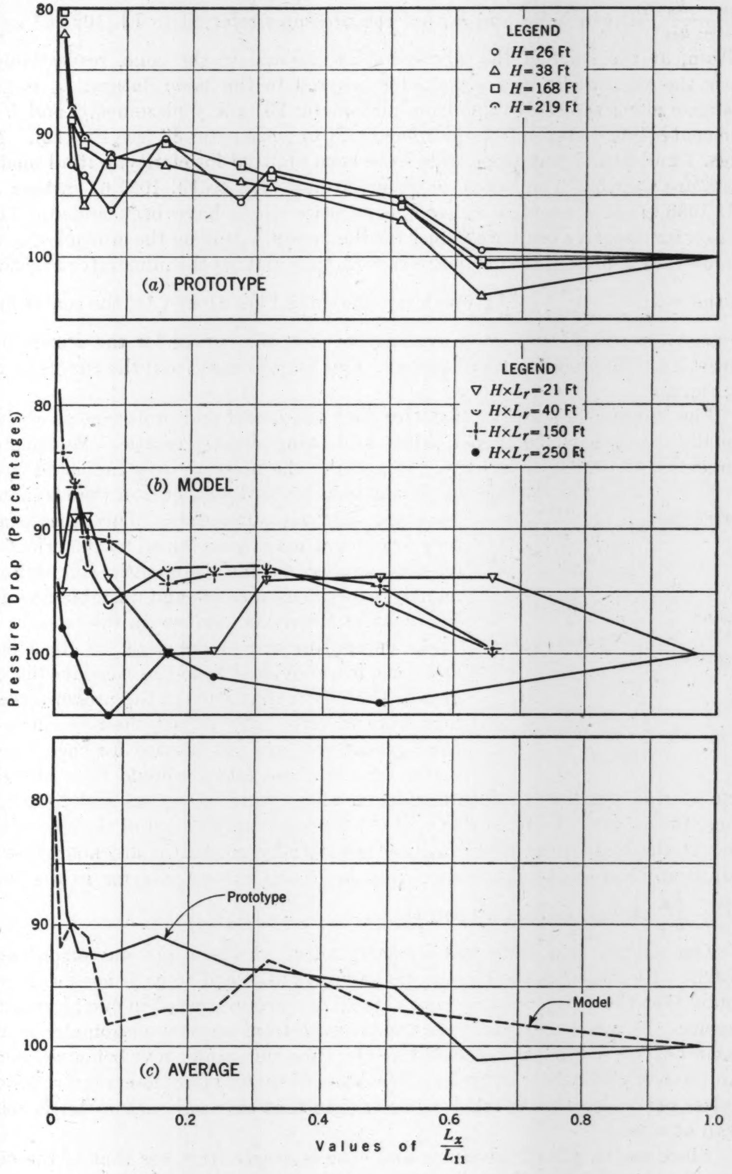

Fig. 8.—Comparison of Pressure Drops on Invert of Bellmouth

$\frac{h_{23} - h_x}{h_{23} - h_{33}}$, in which h_{23} and h_{33} are the pressures referred to El. 1021.67 as a datum, at the start of the elbow and at the end of the cone, respectively; h_x is the pressure at any piezometer referred to the same datum; L_x is the distance along the center line from piezometer 23 to any piezometer; and L is the center-line distance from piezometer 23 to piezometer 33 (see Fig. 12). In Figs. 7 and 8, two prototype tests have been omitted for clarity, but all model tests are shown. The heads, however, are referred to El. 1021.67 instead of El. 1036.67, and average center-line pressure drops have been added. The reason for negative ordinate values for the pressure drop on the crown is due to an increase in pressure from piezometer 23, thus making the numerator negative in the ratio $\frac{h_{23} - h_x}{h_{23} - h_{33}}$. Although not shown in Figs. 10 and 11, the center-line pressure drop falls as a good average between the curves for the crown and invert for both model and prototype. This may be seen from the curves given in Fig. 5.

Figs. 10 and 11 show the data for both the model and prototype as almost equally consistent, the model values still being slightly erratic. Reasonable agreement, however, is lacking. In general, the pressure drop indicated from the model tests is about 30% greater than is shown from the field measurements. This unsatisfactory agreement may be explained by the principal reasons applied to the bellmouth comparison; namely, experimental errors and unstable flow for the range of Reynolds numbers in the model.

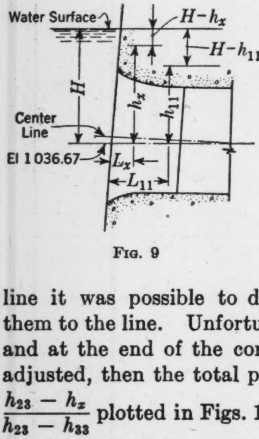

FIG. 9

In computing the model data for the elbow and cone, it was evident from the excessive dispersion of the points that some of the pressure readings were in error. To adjust these, a curve of head versus pressure was plotted for each piezometer. Since these curves should be a straight line it was possible to detect which readings were erroneous and to adjust them to the line. Unfortunately, if the pressures at the start of the elbow, h_{23}, and at the end of the cone, h_{33}, are not initially correct or are not properly adjusted, then the total pressure drop $h_{23} - h_{33}$ causes an error in the ratio $\frac{h_{23} - h_x}{h_{23} - h_{33}}$ plotted in Figs. 10 and 11.

One of the field tests was similarly adjusted where obvious errors were noted. By checking the piezometer numbers attached to each header, it was found that the erroneous readings were all in a group located in one piezometer header. It was concluded that the pressure from another piezometer in the same header was being registered at the time this group was being recorded. An error of this nature is easily made when so many piezometers are required, unless particular care is taken to be certain that only one piezometer is being read at a time.

Since the length of the elbow and cone is nearly six times that of the bellmouth, it is evident that the differences between the model and prototype

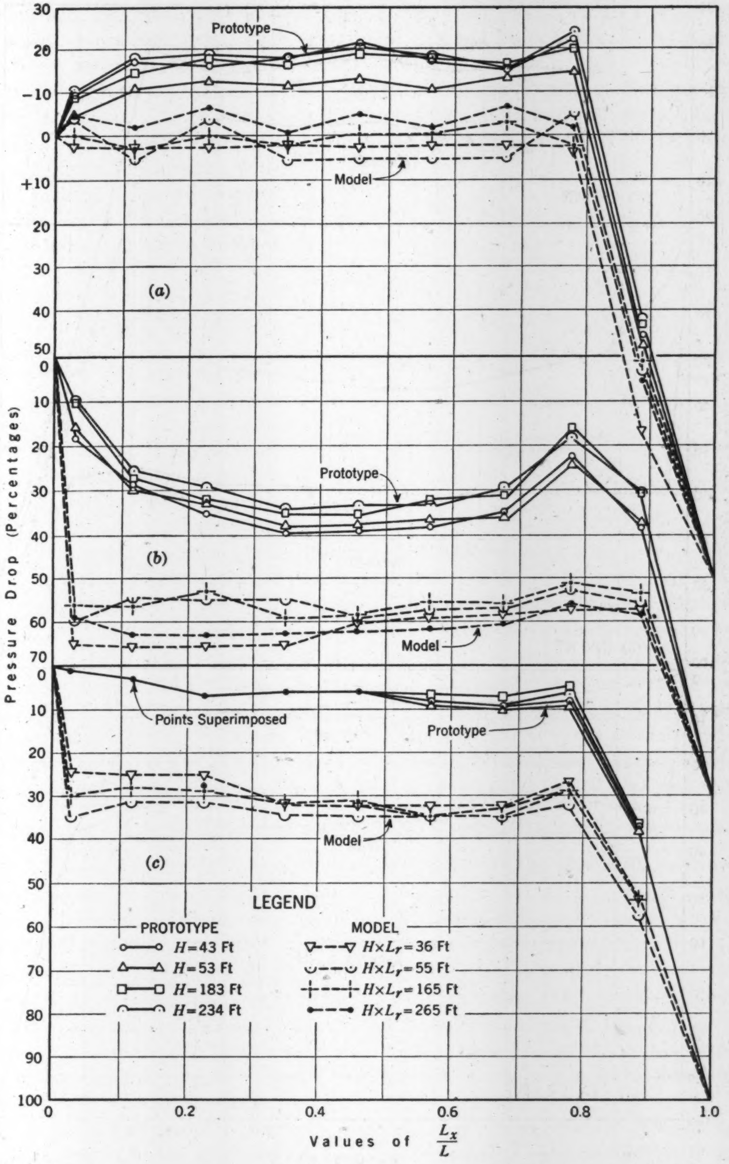

FIG. 10.—COMPARISON OF PRESSURE DROPS IN ELBOW: (*a*) CROWN; (*b*) INVERT; AND (*c*) CENTER LINE

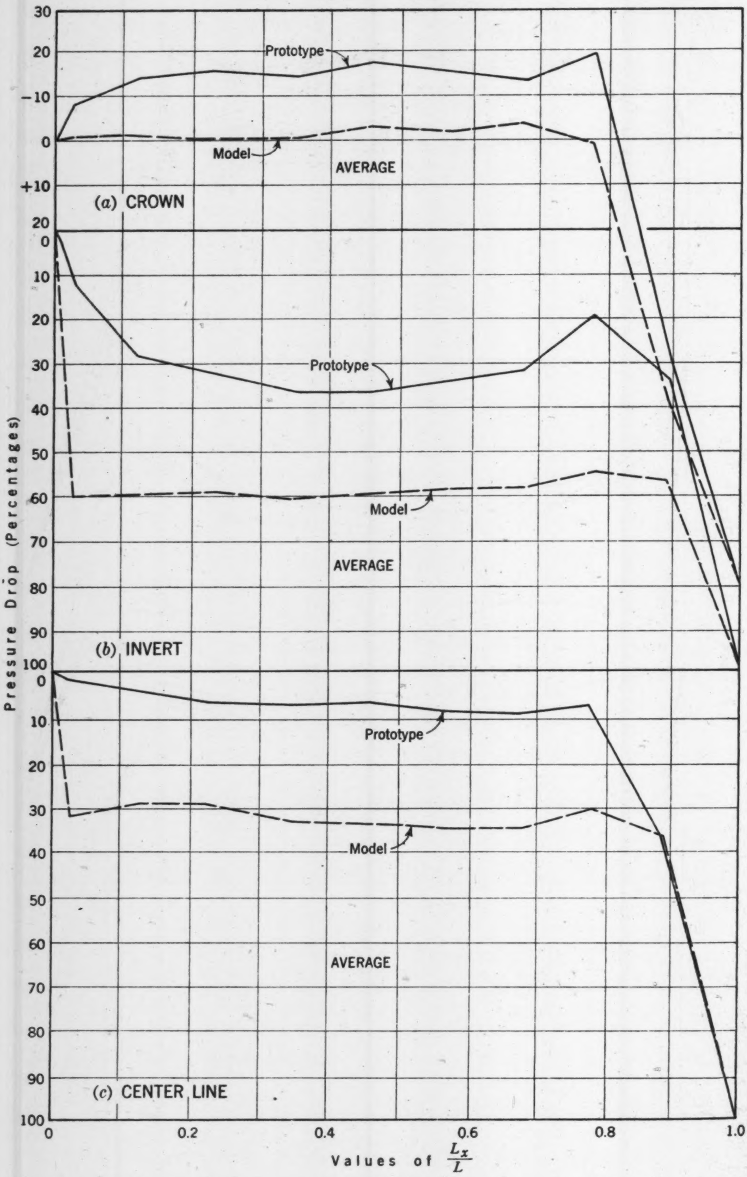

FIG. 11.—COMPARISON OF PRESSURE DROPS IN CONE

friction will have still more effect on the comparison, even though a study of the losses shows the bend loss or centrifugal effect to be considerably greater. The latter seems to be noticeable in the prototype curves in Figs. 10 and 11, where the points are more scattered than for the bellmouth measurements shown in Fig. 9. From tests on other structures, it is known that a slight change of diameter of the cone exit will cause appreciable changes in the pressure gradients through the penstock, making comparison more difficult. Time did not permit a more complete examination of the data for the elbow and cone, which might disclose a more valid method for comparing the pressure drop.

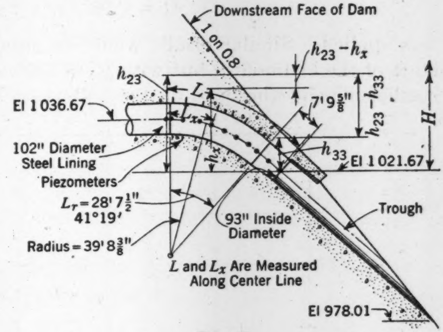

FIG. 12

Discharge Measurements.—The model and prototype discharge comparison is indicated in Fig. 13. Curve 1 is based on the 1 : 17 scale model tests for which $Q_p = Q_m \cdot L^{2.5}{}_r$, whereas Curve 2 is the model rating curve corrected to take into account the difference between model and prototype friction. To make this correction, it was first necessary to estimate an average friction coefficient for the prototype outlet. This was not readily accomplished because of a lack of reliable friction-coefficient data at Reynolds numbers as high as 5×10^7. Nevertheless, it was estimated that a value of 0.0085 for the friction factor would be reasonably accurate. The model friction coefficients and Reynolds numbers were then computed from the laboratory pressure tests and plotted in Fig. 6. Since the model friction is too large, the model heads for given discharges would be too high. Accordingly, assuming that all losses may be scaled to the prototype except friction, the model heads were reduced by the value $(f_m - f_p)\dfrac{L}{D} \times \dfrac{V^2}{2g}$, in which f_m was obtained from Fig. 6 and $f_p = 0.0085$ as estimated. After the pressure data for the prototype became available, the friction coefficients and Reynolds numbers were computed and plotted in Fig. 6. The average value for f_p was 0.0095 as compared to an estimate of 0.0085. Two 40-ft reaches were used for the prototype computations, starting at a distance of approximately eight diameters downstream from the entrance of the outlet, corresponding reaches being used for the model computations. That this is probably not a sufficient length to develop a normal velocity distribution is seen in Fig. 6, where the upper points were obtained using the first 40-ft reach, whereas the lower points were obtained from the following 40-ft reach.

The discharges given by Curve 3, Fig. 13, which were used for computing the prototype friction factors and Reynolds numbers, were developed from prototype pressure measurements, treating the bellmouth as a submerged orifice. The average pressure heads measured at piezometer ring 11 enabled the values of h_e to be computed (see Fig. 4(*a*)). The four piezometers at this point are located 4 ft $5\frac{3}{16}$ in. from the entrance and at the tangent between the bellmouth and transition immediately downstream, as shown in section in Fig. 4. Using the area of the bellmouth at this point, and assuming a coefficient of discharge, the nozzle formula

$$Q = 0.98\, A_{11} \sqrt{2\, g\, h_e} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

was applied. Similar results would be obtained using h_e and the area at the start of the bellmouth, but with $C_q = 0.60$, or by applying the same area and coefficient with the head on the bellmouth reduced by the losses in the bellmouth instead of h_e. These computations are based on the premise that the bellmouth fits the jet from a sharp-edged orifice placed in the plane of the upstream face of the dam.

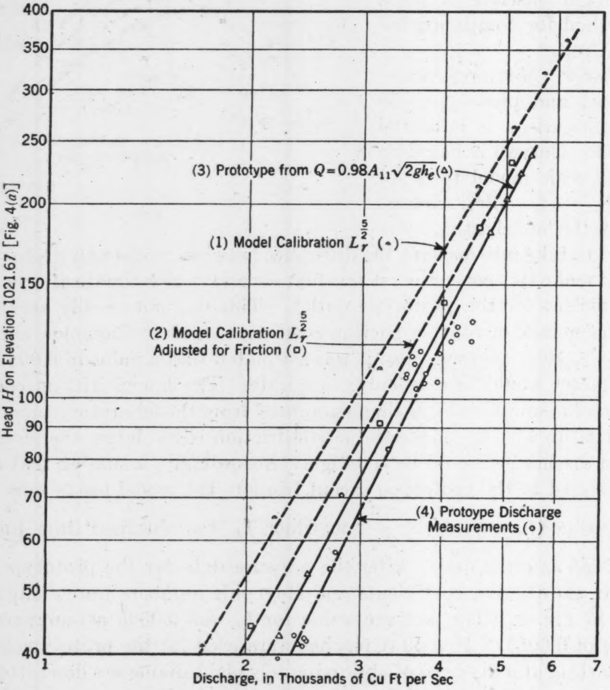

Fig. 13.—Comparison of Discharges

Curve 4, Fig. 13, was obtained from discharge measurements at a river gaging station one-half mile downstream from the dam. Since it is impossible to pass the flow of the river[3e] through only one outlet, the discharge applicable to a single outlet had to be computed by an indirect method. First, a rating curve was obtained for one lower outlet before the water surface in the reservoir reached the intermediate outlets. This was accomplished by plotting effective head (reservoir elevation minus tailwater elevation at the gaging station) against the discharge for one lower outlet (total measured discharge divided by the number of lower outlets operating). As soon as the intermediate outlets began to operate, the total river discharge increased accordingly, but knowing the effective head on the lower outlets and the number operating, it was possible to obtain the discharge per outlet from their rating curve, and thus the total discharge contributed by the lower outlets. Subtracting this value from the measured flow in the river, and dividing by the number of intermediate outlets operating, gave the discharge for one outlet as shown by Curve 4.

[3e] Columbia River.

This method assumes that each outlet will discharge the same amount, and that the jets from the intermediate outlets will not affect the effective head on the lower outlets. Although these assumptions are not strictly correct, it is believed that Curve 4, Fig. 13, and certainly Curve 3, would agree within 5% of any rating curve obtained by measuring the discharge of only one outlet.

In comparing the four rating curves over a range of head of from 230 ft to 50 ft, the uncorrected model discharge (Curve 1) is from 10% to 21% less than the prototype discharge computed at the bellmouth (Curve 3), whereas the corrected model discharge (Curve 2) is only 3% to 8% less. Similarly, the uncorrected model discharge (Curve 1) is from 11% to 27% less than the measured prototype discharge (Curve 4), whereas the corrected model discharge (Curve 2) is only 5% to 15% less.

Summary.—The agreement between the model and prototype in this quantitative comparison is reasonably good except in one instance. Considering experimental errors and lack of similitude relative to Reynolds' number, the pressure drop in the model bellmouth agrees with the prototype within 5%; the pressure drop in the elbow and cone of the model, on the other hand, is 30% greater than in the prototype; and, finally, the model estimate of the prototype discharge is, on an average, 8% low. Even though complete accord could not be obtained, the 1 : 17 scale model estimates are on the safe side and the field measurements show that an excellent prototype design has been evolved. It follows, therefore, although complete similitude was lacking, that the model could be relied upon to prove not only the inadequacy of several proposed designs, but also to develop the satisfactory design finally adopted.

CONCLUSIONS

To make better model-prototype comparisons, it is evident that plans should be prepared for procuring field measurements during the model tests and while the prototype is being designed. This not only enables a sufficient range of model data to be obtained, but it also makes certain that the instruments required at the prototype will be located properly and incorporated as a part of the design of the structure. Even these precautions may not yield the desired results because of the difficulties in actually obtaining prototype flow measurements. Thus, the reasons for so few quantitative comparisons are traced to the necessity of waiting years before sufficient water is available, or to the difficulties in measuring large discharges and high velocities, or to the fact that the measured discharge is derived from several sources instead of the one to be used in a comparison. Finally, the model experiments themselves introduce objectionable factors influencing comparisons, the chief one being the inability to test the model of conduits at the correct range of Reynolds numbers. In any event it is important to build hydraulic models to as large a scale ratio as possible.

The qualitative and quantitative examples of model-prototype comparisons given in this paper reaffirm the high degree to which the model can be relied upon. Although the avowed purpose of any comparison, particularly the quantitative type, should be to affirm the theory of hydraulic models or to modify the transference relations if necessary, it cannot be accomplished from only a few comparisons. At present, the emphasis should be laid on the limitations and accuracy of quantitative estimates based on model tests. In this regard, it is equally important to show both inferior and good model-prototype comparisons. The lessons learned therefrom will certainly demonstrate the adequacy of present-day model research.

ACKNOWLEDGMENTS

The material used for this paper represents the efforts of many individuals in the laboratory and field. The 1 : 17 scale model tests were conducted by D. M. Lancaster, Jun. Am. Soc. C. E. The planning of the prototype piezometer installations and field tests was done by C. W. Thomas and J. W. Ball, Assoc. Members, Am. Soc. C. E. The field tests were made by L. J. Snyder and A. F. Myers. D. J. Hebert contributed valuable suggestions for presenting the data. All tests were under the direction of the senior author in the materials, testing, and control division which is supervised by R. F. Blanks and Arthur Ruettgers, Members, Am. Soc. C. E., senior engineers. Design studies and investigations are under the direction of J. L. Savage, Hon. M. Am. Soc. C. E., chief designing engineer. S. O. Harper, M. Am. Soc. C. E., is chief engineer of the Bureau of Reclamation, and J. C. Page, M. Am. Soc. C. E., is commissioner of Reclamation. E. W. Lane, M. Am. Soc. C. E., at the University of Iowa, and the staff of the U. S. Waterways Experiment Station, Vicksburg, Miss., contributed many of the references that comprise the Bibliography at the end of this Symposium.

A DRY-DOCK SUCTION CHAMBER

BY C. B. PATTERSON,[4] JUN. AM. SOC. C. E.

SYNOPSIS

Other papers of this Symposium describe studies in which the analyses of model and prototype data could be based upon direct quantitative comparisons. This paper will be devoted to a study wherein, due to the lack of certain measurements in the prototype, the comparison of model and prototype performance was approached from an inductive standpoint. The problem under investigation was the unsatisfactory operation of pumps used to drain a large dry dock; the medium of study was a 1:10-scale model constructed at the Waterways Experiment Station.

The dry dock, together with its culvert system and suction chamber, is shown by the general plan drawing in Fig. 14. (Interconnecting passages to the suction chamber from adjacent dry docks are not shown.) The suction chamber is shown in greater detail in Fig. 15, and the arrangement of pump intakes (1, 2, and 3) and sluice gates (3, 4, and 5) is indicated. This arrangement, the high rate of discharge (130,000 gal per min maximum per pump), and the limited dimensions of the suction chamber, gave rise to unstable and sometimes violent flow conditions, which were manifested at the pumps by vibration, loss of capacity, and symptoms of cavitation. (All such objectionable features will be covered by the general term "rough operation.") Test runs in the prototype yielded notes and observations as to the character of pump performance, but did not provide any numerical data or evidence as to the character of flow within the suction chamber.

In constructing a model for the investigation, it was essential that the proper distribution of flow through the three sluice gates be assured. Accordingly, the entire system of side culverts and inlets was reproduced in the model. It was not feasible to reproduce the prototype pumps by means of miniature pumps of a homologous series; however, the proper metered discharges were induced through the intakes by ordinary centrifugal pumps. For purposes of visual observation, the suction chamber and pump intakes were made of transparent pyralin.

To gain some idea as to flow conditions within the suction chamber, compressed air was injected into the model under operating conditions similar to those known to give unsatisfactory pump operation in the prototype. From observations of the air bubbles in these preliminary tests it was learned (*a*) that flow entering the suction chamber from the sluice gates created initial rotation about one or another of the pump intakes (depending upon the particular conditions of operation), and (*b*) that initial vortices so formed were accentuated as the water was drawn upward into the bellmouth intakes. Under such conditions it was reasonable to expect that the pressure at the axis of any intake so

affected (that is, at the center of the vortex) would frequently fall below the suction lift capability of the pump. It was concluded that the rapid and violent fluctuations of pressure attending vortex action within the intakes were responsible for an alternate breaking and restoring of suction head at the pumps, resulting in the aforementioned symptoms.

To support this conclusion, and to provide a basis for the comparison of model and prototype performance, it was desired that a record be made of the amplitudes and frequencies of pressure fluctuations within the pump intakes. It was believed that such data would permit the establishment of a criterion for pump operation, whereby rough pump operation would be revealed by a record showing fluctuations of great amplitude and frequency, and whereby smooth operation would be indicated by slight variations of pressure. From such a criterion, the model reproduction of prototype performance could be confirmed, and the effectiveness of any corrective measures under trial could be evaluated.

To obtain a record of pressures within the suction bells, the instrument shown in Fig. 16 was devised. The operation of this instrument is very simple: Pressure impulses originating at the pitot-tube opening are transmitted through the confined liquid in the tubing to the face of the pressure cell; the resulting deflections of this diaphragm are recorded electrically by an oscillograph to give a continuous time-record of the instantaneous values of pressure.

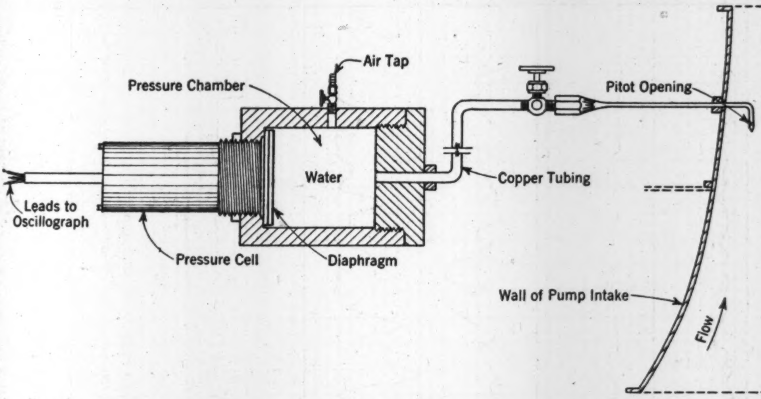

Fig. 16.—Device for Measuring Rapid Fluctuations of Pressure

Using this instrument the model was run under each operating condition—combination of pumps and sluice gates in operation—for which observations had been made in the prototype. Oscillograph records taken during a few such tests are plotted in Fig. 17; and for each of the test conditions the observations made under comparable conditions in the prototype are recorded in Table 1. (In Fig. 17, and all other figures, dimensions are expressed in terms of prototype equivalents.) By comparison of model and prototype observations it may be seen that they are consistent in all cases. Furthermore, the criterion for rough and smooth pump performance is definitely established. From such a model-prototype comparison it was safe to assume that predictions as to the effectiveness of corrective measures could be relied upon.

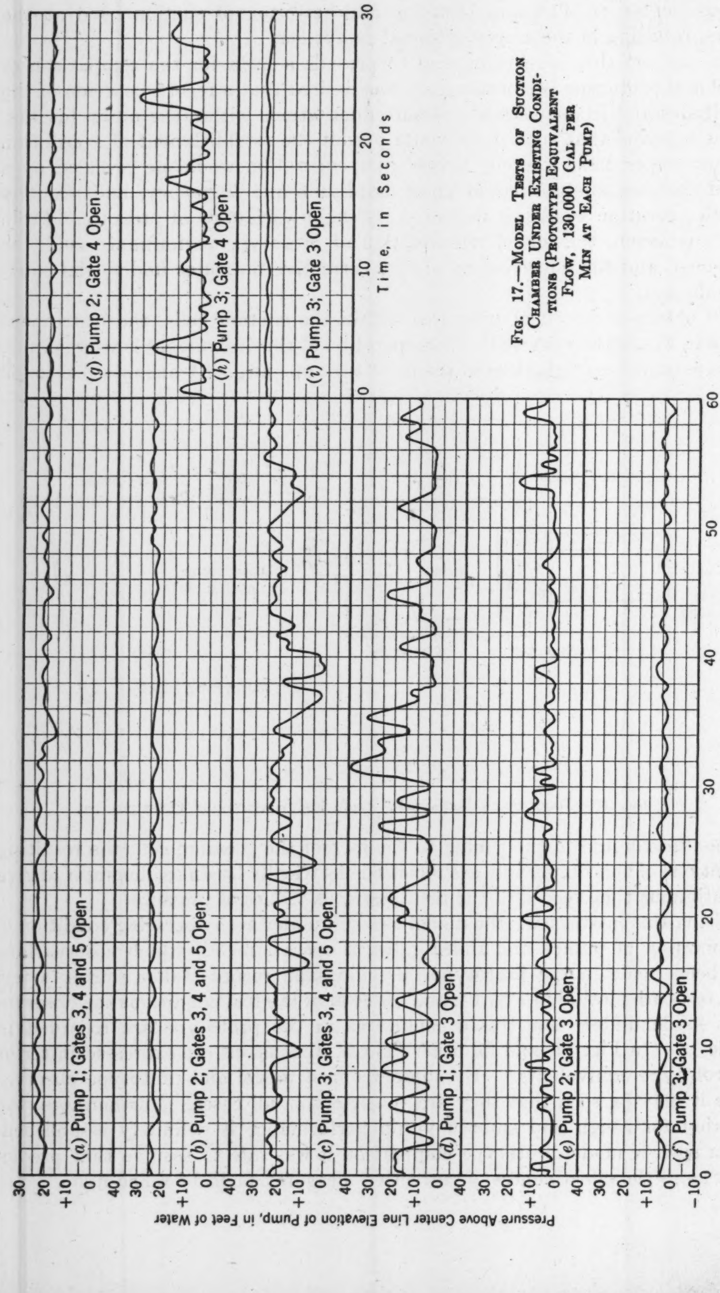

FIG. 17.—MODEL TESTS OF SUCTION CHAMBER UNDER EXISTING CONDITIONS (PROTOTYPE EQUIVALENT FLOW, 130,000 GAL PER MIN AT EACH PUMP)

It was considered that the unsatisfactory performance of the pumps would be improved if the vortices in the intakes could be broken up. For this purpose, vertical vanes of the design shown by Fig. 18 were installed in the model pump intakes. In order that flow in a longitudinal direction be unobstructed, transverse vanes were not extended to the floor of the model suction chamber. In the prototype, however, all vanes were extended to the floor. The results

Fig. 18.—Design of Vanes for Pump Intakes

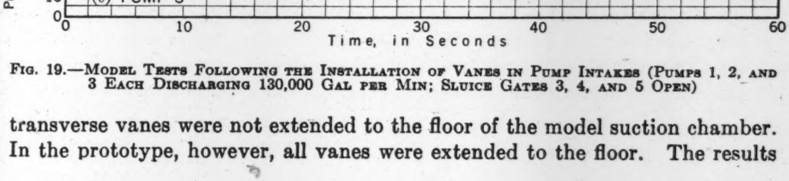

Fig. 19.—Model Tests Following the Installation of Vanes in Pump Intakes (Pumps 1, 2, and 3 Each Discharging 130,000 Gal per Min; Sluice Gates 3, 4, and 5 Open)

of a model test run with these vanes in place are shown in Fig. 19. By comparing these results with those of Fig. 17, the improvement is evident, and a smooth operation of the pumps is indicated. Modifications of the basic design vanes were also tested, but no improvement over the basic design was found.

Accordingly, vanes of the basic design were adopted for installation in the prototype. As a final step in the analysis, the model predictions were thoroughly substantiated by the prototype; it is reported that operation of the pumps, following installation of vertical vanes in the intakes, has been entirely satisfactory. A complete model-prototype confirmation would include the measurement of pressure fluctuations in the prototype but thus far such measurements have not been practicable.

PICKWICK, WHEELER, AND GUNTERSVILLE LOCKS

BY MARTIN E. NELSON,[5] M. AM. SOC. C. E., AND
JAMES J. HARTIGAN,[6] ESQ.

SYNOPSIS

A lock and dam,[6a] one of the major projects constructed on Tennessee River by the Tennessee Valley Authority (TVA), was designed in 1934. A model of the proposed lock was built and tested at the U. S. Engineer Sub-Office, Iowa City, Iowa, for the purpose of aiding in the hydraulic design of the filling and emptying system. As the Tennessee development continued, other locks were designed and models were used to study special problems and to check the final plans.

The question of the reliability of hydraulic lock models in simulating conditions which would exist in the full-size structures developed with the increased use of this method of design. Accordingly, steps were initiated to test a model of an existing lock in which exact geometric similarity could be obtained. The project chosen for the correlation was a lock,[6b] the first project completed in the river by the TVA. A model of the lock was built in December, 1936, and comparisons were made between model tests and a limited amount of prototype test data available at that time. The results of these comparisons were satisfactory, but the prototype data available were not adequate to warrant drawing definite conclusions.

The division engineer of the Ohio River Division initiated steps for testing a number of prototype locks in the Tennessee and Ohio rivers to verify the model tests and to study, under actual operating conditions, the hydraulics of various modifications of the port and culvert system. Tests were made on Pickwick, Wheeler, Wilson, and Guntersville locks on the Tennessee River; and No. 41 and Montgomery Island locks on the Ohio River. Model tests had been made on only Pickwick, Wheeler, and Guntersville locks, and this paper will be confined to a discussion of tests made on these three locks and their models.

GENERAL DESCRIPTION OF LOCK HYDRAULICS SYSTEMS

The locks in question are all equipped with the same general type of filling and emptying system. Longitudinal culverts located in the side-walls of the lock open into the upper pool through gallery intakes and into the lower pool through similar discharge sections. Short lateral ports connect the culverts with the lock chamber near the floor. The flow in each culvert is controlled

FIG. 20.—GUNTERSVILLE PROJECT LOCK

by valves upstream from the first and downstream from the last lateral port to the chamber. In filling the lock chamber the downstream valves remain closed, the upstream valves are opened at a prescribed rate, and water from the upper pool enters the culverts through the intake galleries and flows into the lock chamber through the short lateral ports, the flow of water continuing until the water levels in the chamber and upper pool are equalized. To empty the lock the upper valves are closed, the lower valves opened, and water in the chamber discharges into the lower pool until their levels coincide.

Fig. 20 shows the essential details of the hydraulic system of Guntersville Lock. The intake galleries and culverts are designed to effect as uniform acceleration of the flow as possible from the face of the lock wall to the valve section. The ports (see Fig. 21) were streamlined with well-rounded entrance corners to eliminate separation of the jets from the leeward walls. The bores were tapered to effect greater discharge capacity and to reduce turbulence in the chamber by expanding the jets and decreasing their velocity. The discharge section was also designed with a view to obtaining uniform distribution of discharge in the lower lock entrance and to minimize turbulence in the immediate area.

HORIZONTAL SECTION

VERTICAL SECTION

(b) DISCHARGE PORTS

Fig. 21.—Sections Through Lock Ports, Guntersville Lock

Pickwick Lock has a system essentially identical to that in the Guntersville Lock, only enlarged in scale in approximate proportion to the relative dimensions of the structures.

The hydraulic system of Wheeler Lock is typical of the designs used in inland waterways locks prior to the use of models in analyzing the hydraulics involved in their operation. Deviation from perpendicular lines to effect better hydraulic efficiency was practically avoided. Simplified construction was given primary consideration at the expense of efficiency throughout a lifetime of operation.

Scope of the Tests

The parallel tests that were made in corresponding model and prototype locks will be described in general terms in order to eliminate the necessity of discussing the experimental work performed on each individual structure. Each type of test considered was performed on at least one pair of similar locks and in most cases on all three pairs considered in this paper:

(*a*) The stages near both ends of the lock chamber were observed with respect to time in filling and emptying operation. From these data were plotted filling or emptying curves, rate-of-rise or rate-of-fall curves, and water-surface slope curves, all with respect to time. Comparisons of model and prototype were made on the basis of total time required to complete the operation, the coefficients of discharge for the entire hydraulic system, the maximum value of the rate of change in stage in the lock chamber, and the rate of decrease in the flow after the maximum had been reached as indicated by the slopes of the rate of rise or fall curves.

(*b*) Velocities were observed in the ports of the intake section, the manifold section, and the discharge section, and from these data comparisons of the distribution of discharge in the respective sections were made.

(*c*) Pressure measurements observed at the ends of the culvert transition sections were used in conjunction with volumetric discharge measurements in the lock chamber to determine discharge calibrations and venturi coefficients.

The primary use for hydraulic models is to provide data for design. As such, the functions of a model are generally completed before the prototype is built, and not infrequently the final design is modified from that used in the model, due to contingencies which had not arisen until the final stages of the design were reached and which were considered too insignificant to warrant the expense of checking in the model. As a result, very few prototypes are built exactly like the models from which their designs were developed. Such differences were found in the locks covered by this study, but wherever possible, corrections will be applied or dimensionless parameters used to validate the desired comparisons.

Comparison of Prototype and Model Tests, Pickwick Lock

Intake Ports.—A primary consideration in the design of the intake sections of one lock[6c] was a uniform distribution of flow in the ports. With flow in one direction only, a tapered culvert section could be used. That the design successfully approximated a uniform distribution in the four ports on one side of the culvert, and that agreement existed between model and prototype distributions, are indicated by the graph in Fig. 22. The discharge in the model intake ports varied uniformly from 21.5% to 28.5% and in the corresponding prototype ports from 22% to 27%.

[6c] Pickwick Lock.

Transition Section.—The rating equation for a culvert transition section, expressed in terms of culvert discharge Q and pressure head differential between two sections $h^{0.5}_p$, is based on the Bernoulli theorem; thus:

$$Q = K\,h^{0.5}_p \qquad (3)$$

The coefficient of discharge for the transition section meter is equal to the ratio of the observed to the theoretical rating. A comparison of prototype and

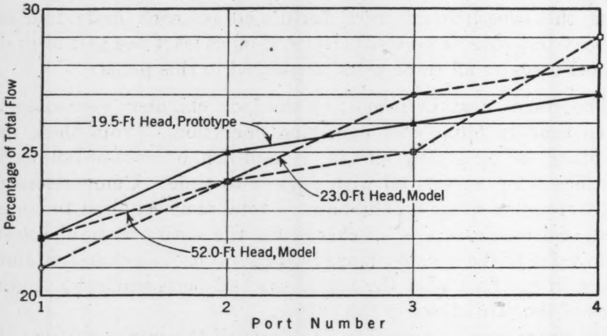

FIG. 22.—DISTRIBUTION OF FLOW THROUGH INTAKE PORTS, PICKWICK LOCK (CONSTANT FLOW)

model locks is made, as shown in Table 2, on the basis of the performance of their culvert transition sections as flow meters. The lack of exact geometric similarity in the transition sections of model and prototype accounts for the small difference in the constants of the theoretical rating equations; however corresponding equations and coefficients for model and prototype are in virtual agreement.

TABLE 2.—COMPARISON OF MODEL AND PROTOTYPE LOCKS

Description	Rating Equation (Eq. 3)		Coefficient of discharge C
	Observed K_o	Theoretical K_t	
Model	1,400	1,500	0.93
Prototype	1,410	1,525	0.92

Lock Stage Tests.—The levels of the water surface in the lock chamber at respective time intervals during filling operations in the model and prototype are shown in Fig. 23. The points defining the filling curves are averages of two stage measurements, one near each end of the lock chamber, observed at each time interval.

The filling curves for the model and prototype locks indicate a considerable difference in the total time of operation and in the form of the filling curves. There were two factors which materially affected the results of these tests—one a difference in construction of the lock-chamber ports (Fig. 24), and the other a difference in the time of opening the culvert valves. In the model the total cross-sectional area of the lock-chamber ports at the smallest section was 125.0 sq ft per culvert, whereas in the prototype the corresponding areas were 145.0 sq ft in the river wall and 147.8 sq ft in the land wall. The culvert valves in the model were opened in a time corresponding to 2 min in the prototype, whereas in the filling test shown the right valve of the prototype required 5 min 4 sec to open, and the left valve 6 min 37 sec. A third factor which also affected the filling time was a difference in the lifts. In the model a lift of 61 ft was simulated, whereas in the prototype 55 ft was the maximum difference in water levels existing during the period of the tests.

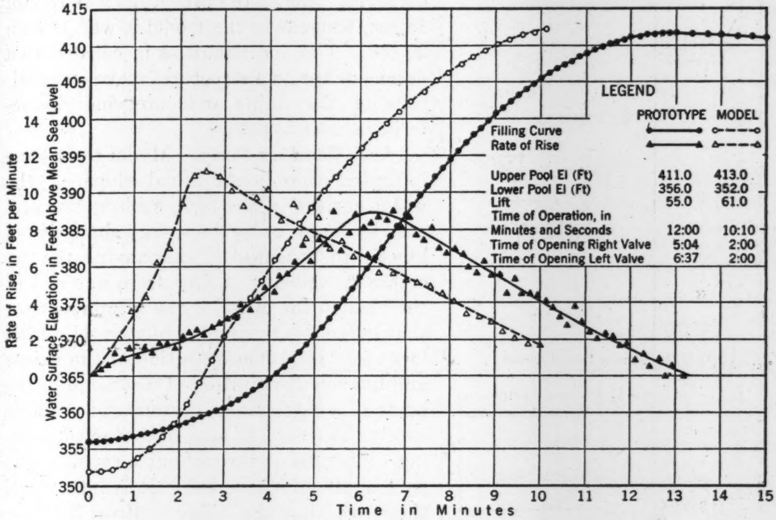

FIG. 23.—FILLING CHARACTERISTICS, PICKWICK LOCK

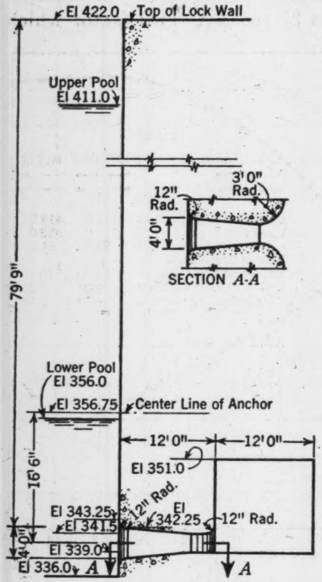
If the two filling curves shown in Fig. 23 were matched at the instant when the corresponding locks were full, it is noted that they would follow approximately the same path for the period after the valves were completely open. The larger throat area in the prototype lock-chamber ports, which tended to increase the efficiency of the prototype over that of the model, appears to have been offset for the most part by the larger and more efficient divergence angle in the model ports.

The maximum rate of rise or fall of the water level in a lock occurs shortly after the culvert valves are fully open. Because of the difference in time of valve operation, the rate-of-rise and rate-of-fall curves for the model and prototype of one of the locks[6c] differ considerably. The maximum rate of rise in the model was 11.1 ft per min at 2 min 35 sec, and in the prototype it reached 9.0 ft per min at 5 min 25 sec. In a manner similar to the filling curves, the rate-of-rise curves for model and prototype follow nearly parallel paths after the peak rate has been reached; the average slope of the curve for the prototype is 1.40 ft per min^2, while that for the model is 1.24 ft per min^2.

[6c] Pickwick Lock.

The differences in construction details and valve operation, noted in the discussion of the filling tests, apply also with respect to the emptying tests. However, the larger port area and smaller lift existing in the prototype, tending to reduce the emptying time, were practically offset by the longer valve period. The emptying time in the prototype was 13 min 18 sec, whereas in the model it was 13 min 29 sec. The dissimilarities in construction details of the two structures make comparisons of the filling and emptying characteristics unsatisfactory.



SECTIONAL ELEVATION

FIG. 24.—SECTIONS THROUGH CENTER LINE OF LOCK-CHAMBER PORT (20 PORTS IN EACH WALL)

Lock-Chamber Ports.—Model tests have indicated that longitudinal slope of the water surface in the lock, such as was created by surges or by the energy change from kinetic to potential accompanying the decrease in velocity of flow from one end of the lock to the other, is the primary factor that influences movement of a vessel during lockage. Improper operation of the valves and uneven distribution of discharge in the ports of a side culvert system will promote surging in the lock; and, once started, surging will continue throughout a considerable part of the filling period. It is important, therefore, that the filling controls be operated so as to eliminate a sudden inrush of water at the beginning of the filling period, and that the system be designed to distribute the lockage inflow evenly among the lock-chamber ports.

From the port velocity tests made in the model and prototype locks,[6e] distribution-of-flow graphs for the ports in the right or river wall for the filling operation were plotted as shown in Fig. 25(*a*). The flow distributions in the model and prototype differed considerably, due largely to the dissimilarity of the ports. In earlier laboratory experiments it was found that the distribution of discharge from the ports during a filling operation was influenced to a large extent by the value of the cumulative cross-sectional area of the lock-chamber ports at the smallest section. When the port area exceeded a certain value, the shape of the hydraulic gradient was changed so that during part or all of the filling period water would flow from the lock chamber into the culvert through a number of the ports at the upstream end of the manifold. The prototype port area exceeds that of the model by 16% in the river wall and 18.2% in the land wall. Excess area in the prototype is equivalent to that of three ports. The effect of the excess port area in the prototype is indicated in Fig. 25(*a*). Discharge through ports 1 and 3 was reversed, flowing from the lock chamber into the culvert during the entire period of the filling

---

[6e] Pickwick Lock.

operation, and, although the flow in port 2 was not measured, it undoubtedly was negative also. Therefore, the distribution patterns for the filling operation in the model and prototype manifolds cannot be correlated.

[a] Discharge refers to flow into, and out of, lock chamber through the ports in the river wall. [b] Prototype. [c] Model.

FIG. 25.—DISTRIBUTION OF FLOW, LOCK-CHAMBER PORTS, PICKWICK LOCK

A very close similarity in the flow distribution in the model and in the prototype during emptying operations is shown in Fig. 25(*b*). The distribution of flow through the ports was only slightly affected by variations in head, and the discrepancies in port dimensions in the prototype had less effect in the emptying than in the filling operation, undoubtedly because the flow in the venturi-shaped ports was converging instead of diverging.

Velocity in Discharge Ports.—The discharge sections of Pickwick Lock, with the exception of slight differences in a few dimensions, were constructed like the model. Flow conditions during the first part of the emptying operation differed in the two structures, but after the valves were opened completely, distribution of the flow from the ports was found to be quite similar.

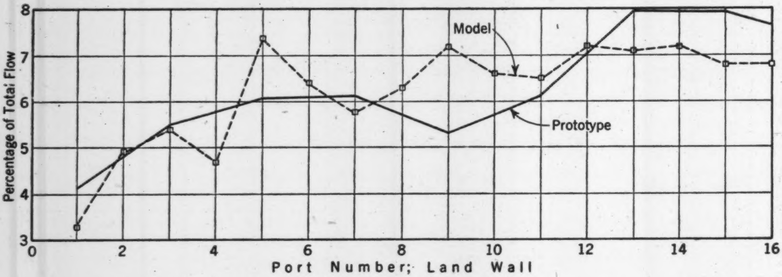

FIG. 26.—DISTRIBUTION OF FLOW, DISCHARGE PORTS, PICKWICK LOCK (EMPTYING OPERATION)

In Fig. 26 is shown the distribution of flow from the discharge ports in the land wall of the model for a head of 39 ft. The curve for the prototype shows an average distribution for four heads (25 ft, 21 ft, 15 ft, and 10 ft), all of which occurred after the valves were open and flow conditions were relatively stable.

These curves for model and prototype are similar in having the same general trend of larger discharges in the downstream ports. The increase in the discharge for each successive port downstream is not so orderly in the discharge section (which has a culvert of variable area) as it is in the lock-chamber section which has uniformly spaced ports and constant area culvert. The percentages of culvert flow carried by the eight upstream and eight downstream ports of the discharge section were 44.4% and 55.6% for both model and prototype, variations between model and prototye having balanced in each half of the section.

Lock Coefficients.—The coefficients for lock hydraulic systems presented in this paper were computed for the period after the valves were fully opened and were based on the minimum culvert area. In the prototype lock system the section having the least area through which the water passes, both in filling and emptying, is the 12-ft by 12-ft culvert below the transition section. In the model the section of minimum area was at the throat of the lock-chamber ports, this area being 250 sq ft as compared with the minimum culvert area of 288 sq ft. The culvert area in the prototype was the same as in the model, but the cumulative port area at the minimum section was 292.8 sq ft.

FIG. 27.—LOCK COEFFICIENT, PICKWICK LOCK

The lock coefficient C_l, which is a bulk coefficient representing the efficiency of the lock, is equal to the ratio of the observed discharge to the theoretical discharge computed by the plain orifice equation using instantaneous heads:

$$C_l = \frac{v_l A_l}{A_c \sqrt{2 g h}} \tag{4}$$

In Eq. 4: v_l = the lock-chamber rate of rise or fall; A_l = lock-chamber area; and A_c = cross-section area of two culverts. The filling and emptying coefficients determined for the Pickwick prototype and model locks are shown in Fig. 27 and Table 3.

[a] Maximum rate of rise or fall. [b] Maximum water surface slope. [c] Distribution based on equal number

The average coefficient for filling the prototype lock based on the culvert area, which is the smallest section in the course of flow, was 0.91 as shown in the legend. In the model the coefficient based on the culvert area was 0.87. However, the smallest area in the course of flow in the model was at the throat of the ports, and when the model coefficient is correlated to the prototype value by applying the ratio of culvert to port area, 1.15, it is increased to

1.00, which is not in agreement with the prototype value. It would appear that the venturi type flow in the ports during filling makes a comparison of the lock coefficients unsatisfactory because the divergence effect in the model and prototype was not the same.

The average coefficients for the emptying operation, based on the least culvert or port area, are for the prototype 0.73 and for the model 0.64 × 1.15, or 0.74, which are in agreement within 2%. The flow through the lock-chamber ports during an emptying operation is a converging flow, and the decrease in the efficiency of the model as indicated by the lock coefficient is directly proportional to the reduction in the area of the controlling section.

of ports upstream and downstream. [d] Model test at Norris Laboratory.

In the orifice equation, used in computing lock-chamber discharge,

$$Q = C A \sqrt{2 g h} \qquad (5)$$

the head, h, for filling, is the upper pool elevation minus the lock-chamber elevation, and, for emptying, the lock-chamber elevation minus the lower pool elevation. This head is simply the hydrostatic head and is not the complete effective head acting on the column of water in the culverts. Considering the filling operation, the lock-chamber water surface does not stop when it reaches upper pool elevation but rises above it. Therefore, at the instant when the lock is full the effective head is not zero but has some positive value. When the dynamic head factor is included in the equation for discharge the resulting coefficients for decreasing heads become smaller instead of larger. Thus, in the prototype tests, as shown in Fig. 27, the ascending value of the coefficient as the head decreases can be attributed to the fact that the effective head was not used in the computation, whereas in the model tests the decrease in the coefficients for low heads may indicate that the hydrostatic head is more nearly equal to the effective head in the model than in the prototype.

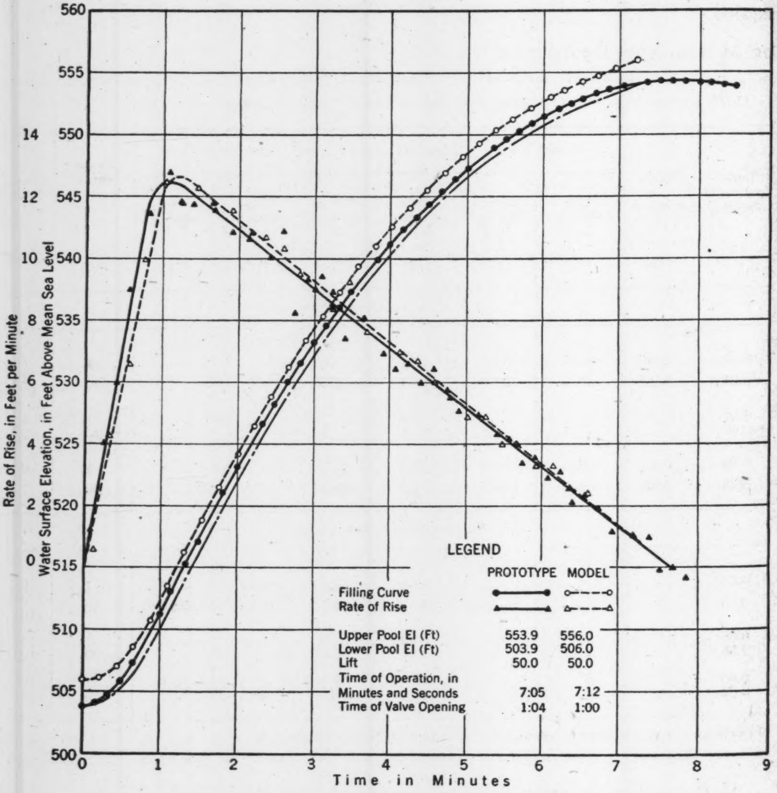

FIG. 28.—FILLING CHARACTERISTICS, WHEELER LOCK

Coefficients based on the effective head (that is, static plus dynamic) and coefficients based on static head alone have the same adverse characteristic of not being entirely constant throughout the lock operation. On the other hand, the effective head is not so easily measured as the static head. In view of the difficulties of establishing the exact value of the effective head and of the questionable advantage, in the comparison of model and prototype, of the coefficient thus obtained over that based on the static head, all lock coefficients presented in this paper are based on the static head alone.

WHEELER LOCK—COMPARISON OF PROTOTYPE AND MODEL TESTS

Lock Stage Tests.—Stages measured with respect to time during filling operations in the Wheeler model and prototype lock chambers are shown in Fig. 28. The points which define the curves are averages of two stage measurements, one near each end of the lock chamber. Typical sections through the lock-chamber ports are shown in Fig. 29.

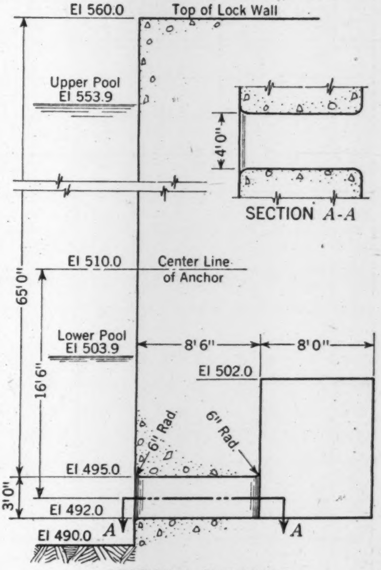

FIG. 29.—SECTIONS THROUGH CENTER LINE OF LOCK-CHAMBER PORT (10 PORTS IN EACH WALL)

In the prototype, it was necessary to make the tests with existing elevations of 553.9 for the upper pool and 503.9 for the lower pool; tests had been made previously in the model with elevations of 556.0 and 506.0, respectively. In each case the head was 50 ft, but the pool levels used in the model were 2.1 ft higher than in the prototype. In Fig. 28 the filling curve of the model is shown as observed and also adjusted to agree with the lower pool elevation of the prototype. The prototype lock filled in 7 min 5 sec, whereas the model filled in 7 min 12 sec. Maximum rates of rise were 12.4 and 12.6 ft per min, and the slopes of the rate of rise curves were 1.90 and 1.94 ft per min^2, respectively.

From emptying tests in the model and prototype locks there was observed about the same degree of agreement in prototype and model emptying characteristics as that shown in Fig. 28 for filling characteristics. Emptying time in the prototype was 7 min 22 sec, and in the model was 8 min 2 sec. Maximum rates of fall of the water surface in the chambers were 11.8 and 11.7 ft per min, respectively, and corresponding slopes of the rate of fall curves were 1.9 and 1.6 ft per min^2.

The valve opening periods were nearly identical in the prototype and model, and the crests of the water surface change curves occurred at about the same time in the two structures. In the filling tests the model was slightly more efficient than the prototype, whereas in the emptying tests the reverse was true.

Velocity in Lock-Chamber Ports.—Distribution of flow in the lock-chamber ports for the left or river wall of the prototype and for the right wall of the

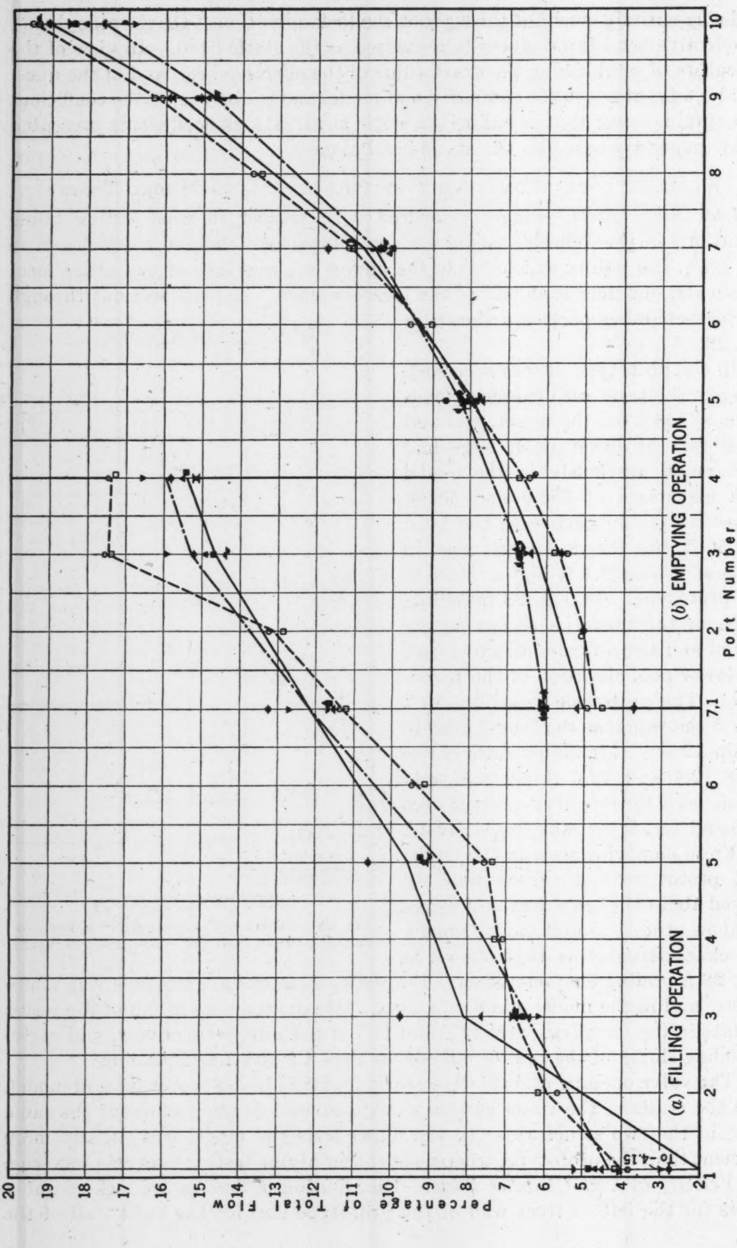

FIG. 30.—DISTRIBUTION OF FLOW, LOCK-CHAMBER PORTS, WHEELER LOCK (RIVER WALL) (SEE TABLE 3A)

model is shown in Fig. 30(*a*) for the filling operation. The curves for the model were based on velocity tests with steady flow through the system, whereas the curves for the prototype were based on velocity measurements made during filling operations. The distribution of flow observed in the lock-chamber ports of the model is in good agreement with that of the prototype (see Table 3*A*). Inflow into the lock through the upstream five ports in the prototype was 32.4% of the total, and in the model 31.3%. The corresponding values for the downstream five ports were 67.6% and 68.7%, respectively.

TABLE 3*A*.—DISTRIBUTION OF FLOW, LOCK-CHAMBER PORTS (RIVER WALL) (SEE FIG. 30)

Description	AVERAGE OF THREE HEADS[b]			AVERAGE OF SIX HEADS[b]						AVERAGE OF TWO HEADS[d]	
	-●-	◓	◒	■	▲	●	◖	◗	▼	□	○
Head, in feet	48	45	40	35	30	24	20	15	10	35	24
Discharge,[a] in Cubic Feet per Second:											
(*a*) Filling operation	..	..	2,430	2,280	2,110	1,920	1,750	1,540	1,260	2,370	1,960
(*b*) Emptying operation	..	..	2,390	2,240	2,040	1,810	1,690	1,460[c]	1,180	2,130	1,760

[a] Discharge refers to flow into, and out of, lock chamber through ports in river wall. [b] Prototype. [c] 16-ft head. [d] Model.

A good agreement is also noted in the distributions of discharge in the lock-chamber ports in emptying operations in the Wheeler model and prototype locks which are shown in Fig. 30(*b*).

Lock Coefficients.—Filling and emptying coefficients for the Wheeler Lock hydraulic system of the prototype and model are shown in Fig. 31. These coefficients are based on observed discharges computed from the average rate-of-rise and rate-of-fall curves and on theoretical discharge computed from stage records (see Eq. 4). The average filling coefficients for heads above 5 ft are 0.61 and 0.62 for the prototype and model, respectively. Corresponding emptying coefficients are 0.58 and 0.56. The lock coefficient varies as the square root of the slope of the rate-of-rise or rate-of-fall curves. For that part of the filling operation for which coefficients were computed, the model had the steeper rate-of-rise curve and the larger filling coefficient, and the prototype had the steeper rate-of-fall curve and the larger emptying coefficient.

As in Pickwick Lock, the pattern of the Wheeler coefficients indicated that there was less difference between the static and effective heads in the model than in the prototype.

GUNTERSVILLE LOCK—COMPARISON OF PROTOTYPE AND MODEL TESTS

Intake Ports.—In the model tests on one lock[6c] it was found that the distribution of flow through the intake ports was fairly uniform and that it was affected only slightly by variations in the head. The intakes used in one model[6c] were also used in another model,[6d] and no further tests were made

in the latter model to determine the distribution of flow through intake ports. In prototype tests of flow distribution at one lock[6d] it was found that the distribution of flow in the four ports on one side of the intake section varied from 20.5% to 28% and that the pattern of flow distribution was similar to that for the Pickwick intake ports.

Transition Section.—The prototype and model transition sections are correlated by using the dimensionless coefficient of discharge because corresponding dimensions of the culvert at which pressure measurements were taken were not similar. Coefficients for the prototype and model transition section meter —0.95 and 0.93, respectively—are in good agreement.

Lock Stage Tests.—Stages with respect to time in the lock chambers (see Fig. 21) during filling operations in the model and prototype are shown in Fig. 32. The time required to fill the lock chamber with a 39.2-ft head in the prototype (5 min 30 sec) was 39 sec, or about 11%, less than the time required to fill the lock chamber in the model. The rate-of-rise curves indicate that the water surface rose faster in the prototype than in the model during the time the valves were opening. It is believed that this difference is due largely to a personal factor introduced in the manual operation of the valves in the model. After the valves are open the rate-of-rise curves are in better agreement, having slopes of 2.77 and 2.57 ft per min^2 for prototype and model, respectively. The maximum rates of rise were 12.7 and 12.5 ft per min in the prototype and model, respectively.

Emptying curves are shown in Fig. 33. The same period of time, 7 min 36 sec, was required to empty the model and prototype lock chambers with a head of 39.0 ft, and the emptying curves were practically identical. Maximum rates of fall in the prototype and model were 8.8 and 9.3 ft per min, respectively, and corresponding slopes of the descending rate-of-fall curves were 1.22 and 1.27 ft per min^2.

Lock-Chamber Ports.—The distribution of discharge in the lock-chamber ports observed in filling operations on the prototype, on the Iowa City model, and on a model of the Guntersville Lock tested in the TVA Hydraulic Laboratory at Norris, Tenn., are shown in Fig. 34.

Velocities measured in the lock-chamber ports of the models with steady flow are shown in the distribution of flow curves as percentages of the total flow. Velocities measured in the lock-chamber ports of the prototype lock during filling operations were plotted against time, and from these graphs the port velocity distribution for a given static head was obtained, using the time interval at which the given static head occurred.

The distribution of flow during the filling operation was better in the models than in the prototype. Percentages of total flow carried by the seven ports in the upstream half of the chamber and by the seven ports in the downstream half of the chamber are: For one model[6e] (average of four heads), 47% and 53%; for another model[6f] (25-ft head), 46.5% and 53.5%; and for the prototype (average of six heads), 40.8% and 59.2%. Patterns of flow distribution in the two models are very similar, and they agree more nearly with that

[a] Discharge refers to the flow into the lock chamber through the ports in the land wall. [b] The curve for the 35-ft head is plotted as a separate line in Fig. 34(*a*), the remaining six in this group being averaged. In Fig. 34(*b*), all seven are averaged. [c] Prototype. [d] Model.

FIG. 34.—DISTRIBUTION OF FLOW, LOCK-CHAMBER PORTS (LAND WALL)

tribution during filling. Percentages of total flow carried by the seven ports in the upstream half, and in the downstream half of the chamber are, for one model[6f] (25-ft head), 44.3% and 55.7%, and for the prototype, 46.5% and 53.5%. The models had the more even distribution during the filling operation, and the prototype during the emptying operation.

Discharge Ports.—Only preliminary tests were made on the distribution of flow in the discharge ports of the Guntersville model. The discharge sections of the Pickwick model were used also in the Guntersville model, and, since the preliminary tests agree with similar data from the Pickwick model, no further tests were considered necessary.

From prototype port velocity tests at one lock,[6d] the distribution of flow in the sixteen discharge ports of the land wall were computed for seven heads ranging from 5 to 35 ft. Distribution of flow among the sixteen discharge ports remained approximately the same for the seven different heads, and the culvert flow carried by the eight upstream and eight downstream ports was 43.6% and 56.4%, respectively, based on the average distribution for the seven heads.

Lock Coefficients.—Average coefficients for the lock hydraulic systems in the prototype and model, for heads greater than 5 ft, are:

Observations on:	Filling	Emptying
Prototype	0.95	0.63
Model	0.88	0.63

For the emptying operation the coefficients are in good agreement, having the same average value for prototype and model, but for the filling operation the prototype coefficients average 8% higher than those for the model.

The prototype ports and the model ports for which data are presented in this paper have the same dimensions at the throat, but the prototype ports are larger at the lock-chamber end. Consequently, the divergence angle for the prototype, 11° 44′, is larger than that for the model port, 7° 50′, and the ports are not geometrically similar. This greater divergence angle is undoubtedly a factor contributing toward the higher coefficients and faster rate of filling observed in the prototype.

Although the area of the culverts was used in computing coefficients for the lock hydraulic system, the minimum area in the prototype and in the model is the cumulative area at the throats of the lock-chamber ports. If, instead of the culvert area, the minimum port area was used, the average coefficient for emptying would be 0.78. For emptying Pickwick Lock the average coefficients based on least port or culvert area were 0.73 and 0.74 for prototype and model, respectively.

The coefficients for a prototype lock[6d] based on static head gradually increase as the head decreases, and for the model they gradually decrease as the head decreases, until just before the end of the lock operation where values of the coefficient increase sharply.

SUMMARY AND CONCLUSION

In Table 3 the results of model and prototype studies of Pickwick, Wheeler, and Guntersville locks are summarized. It includes operation data and areas of critical sections of the lock hydraulic systems.

Tests on one lock[6b] offered the best opportunity for comparing model and prototype performance because the corresponding structures were geometrically similar and lock operation data were in agreement. Moreover, it will be noted that this lock[6b] had the most consistent agreement between model and prototype of the three locks tested, the only material difference in the performance of the corresponding structures being in the longitudinal slope of the water surface for which readings in the prototype lock were larger than in the model.

For model and prototype locks of Guntersville there was agreement in lock operation data, and the two structures were geometrically similar except at the lock end of the lock-chamber ports. A more efficient filling operation was observed in the prototype than in the model, the former having the greater divergence angle in the lock-chamber ports. Furthermore, during the filling operation, the less efficient model had the more even distribution of flow in the lock-chamber ports. It is of interest to note the performance of Guntersville model and prototype locks during the emptying operation. There was agreement in operation time, lock coefficient, and the distribution of flow in the lock-chamber ports irrespective of the difference in lock-chamber port divergence angles. The throat of the lock-chamber port, for which the cumulative area was the minimum in the system, appeared to be effective as the control section of the system during the emptying operation.

There was less agreement in the performance of one model and prototype locks[6c] because, in addition to dissimilarity in the throat area of the lock-chamber ports, lift and valve time in the two structures were not in agreement. However, the performance of this model and prototype[6c] during the emptying operation, similar to that of other locks,[6d] showed agreement in the lock coefficients based on the minimum areas in the respective systems and in the distribution of flow in the lock-chamber ports.

When geometric similarity does not exist in the important elements of two hydraulic structures it is not expected that their operations should conform to the basic laws of similitude. However, where geometric similarity did obtain, and where analogous functions could be correlated by means of the basic laws, this study substantiates the theory upon which the use of hydraulic models is founded and, it is believed, tends to justify the confidence engineers have placed upon this method of analyzing difficult problems in design and operation within the past few years.

ACKNOWLEDGMENTS

Col. R. G. Powell, then division engineer, Ohio River Division, Cincinnati, Ohio, sponsored the project and authorized the tests on the prototype locks

in December, 1937. The tests were supervised by personnel of the U. S. Engineer Sub-Office, Iowa City, under the direction of the district engineer, U. S. Engineer Office, St. Paul, Minn.

The prototype lock tests were conducted by Marvin J. Webster, Assoc. M. Am. Soc. C. E., of the Iowa City Sub-Office, with the assistance of personnel from the District Engineer Offices in whose areas the respective locks are located. Some of the material presented in this paper has been drawn from a report on the project prepared by Mr. Webster for which acknowledgment is made. Permission to use the data obtained in the prototype lock tests is acknowledged to Col. J. W. Moreland, M. Am. Soc. C. E., district engineer of St. Paul.

BOULDER DAM OUTLET WORKS

BY S. P. WING,[7] M. AM. SOC. C. E.

SYNOPSIS

The principal hydraulic model tests of the dam outlet[7a] works (34), which included flow through the intake tower, penstock turbine, and outlet-valve manifolds, were made on a 5⅝-in. (1 : 64 scale), extremely smooth, sheetmetal model which had a friction coefficient of $f = 0.021$ at a Reynolds number **R** of 80,000 and used a maximum of 2 cu ft per sec of water. Performance and efficiency tests of the 30-ft diameter prototype, utilizing a maximum discharge of 20,000 cu ft per sec with measured velocities up to 90 ft per sec and at a Reynolds number of from 40 to 70 $\times 10^6$, made it possible to obtain data from which various hydraulic features of the model and prototype could be compared. These included loss coefficients for the trashrack, bends, branches, valves, and straight-pipe friction. A full discussion of the data was presented before the hydraulic section at the Annual Convention of the Society in July, 1940 (35). This paper is a summary of such of the results as may be generally useful in hydraulic design, together with suggestions concerning the technique of field measurements which, if found practicable, may make possible better comparisons between models and prototypes in future tests.

The letters in Figs. 35 and 36 indicate points at which measurements were taken. Distances are given in units of pipe diameters, that of the 25-ft section being converted into its 30-ft hydraulic equivalent. Three series of comprehensive tests were run from 1937 to 1939 with heads varying from 213 to 337 ft. During the tests the turbines were shut down, varying discharges being obtained by manipulating the 84-in. outlet valves. Pressures were measured with calibrated Bourdon gages and differential mercury manometers, utilizing the dead-ended penstocks for piezometric connections. Tests showed that such large connections taking off at an angle resulted in the gages registering an excess pressure of 0.04 h_v.

Discharges were obtained by impact-pressure tube traverses at right angles to one another in a 96-in. section of pipe located immediately downstream from a reducer and in front of valve A_1, point K. Utilizing these measurements and the simultaneously measured heads on the other valves, the total discharge for the entire battery of valves was computed. The coefficient of the pitot tube in the formula,

$$Q = \frac{A}{C} \sqrt{2\,g\,H} \qquad \text{(6)}$$

obtained from a still-water rating, was corrected for wall proximity effects and for the effects due to curved streamlines caused by the valve and the obstruction of the streamlined struts used to support the instrument (see Fig. 37). These latter corrections were determined by the photoelastic laboratory of the Bureau of Reclamation, using the electric-analogy method (see Fig. 38). Fig. 39 shows the results found by the laboratory, the close correspondence between the laboratory result and that obtained in the rating channel for 2% obstruction being of interest. Since the obstruction offered by the struts is a variable percentage in each circular lamina of the pipe, separate coefficients were applied to each individual reading of the pitot traverse.

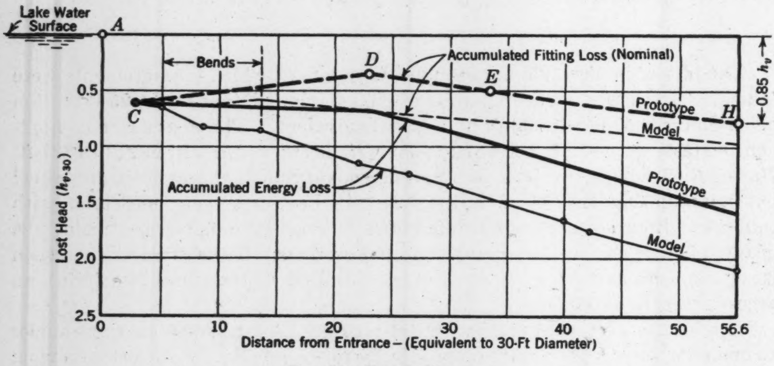

FIG. 36.—ENERGY LOSSES

Plots of the velocity and pressure distribution in the cross section indicated that upstream from the pitot tube the friction in 22.5 diameters of pipe plus a 15% reducer did not introduce enough resistance to normalize the upset velocity distribution due to branching, the velocity contours showing the crescent-like form (typical of flow below a bend) superimposed on the upstream cone of pressure caused by the downstream valve. The latter caused differences in pressure up to 40 ft of water, or nearly 0.5 h_v, between the pipe wall and the center of the pipe. Worth considering in valve design is the fact that the energy of flow was also unsymmetrical, the half of the pipe away from the center of curvature of the branch carrying 10% to 15% h_v more energy than the inside, with the possibility that pressure unbalance existed within the valve.

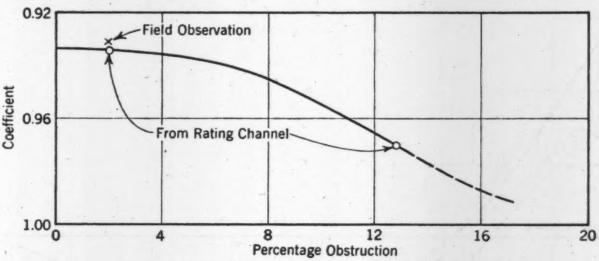

FIG. 37.—PITOT-TUBE COEFFICIENT VERSUS PERCENTAGE OBSTRUCTION

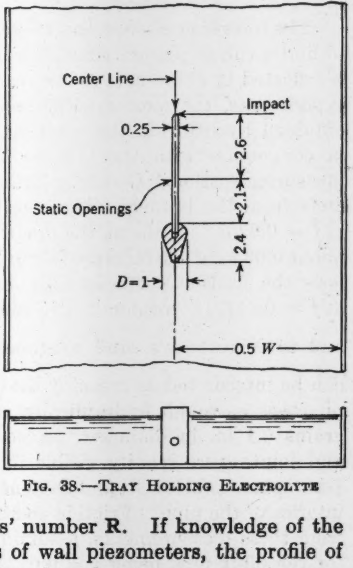

FIG. 38.—TRAY HOLDING ELECTROLYTE

On the whole, the pitot-tube gagings were reasonably self-consistent. An estimate of their errors and a comparison with current-meter gagings in the river indicated a standard error for the largest discharges of the order of 2%.

The interpretation of losses in a penstock, with fittings but relatively few diameters apart, depends upon an ability to separate fitting losses from those due to straight pipe. A pipe entrance or fitting tends to result in a contracted jet of high-velocity water which changes in 20 to 200 diameters downstream to a normal velocity distribution, the length required being dependent on the roughness of the pipe wall and on Reynolds' number **R**. If knowledge of the energy grade is based only on the readings of wall piezometers, the profile of the energy grade characteristically will be found to show an apparent increase in energy in the first 3 or 4 diameters following a fitting, pass through a point of inflection, and then will become concave upward, approaching asymptotically the friction gradient. The model test, moreover, indicated the possibility that nodes of pressure of about 0.03 h_v, located 3 to 4 diameters apart possibly caused by the expansion and contraction of the high-velocity jet, were superimposed on the profile immediately downstream from the branch fitting. This possibility requires more investigation before it can be taken as a fact.

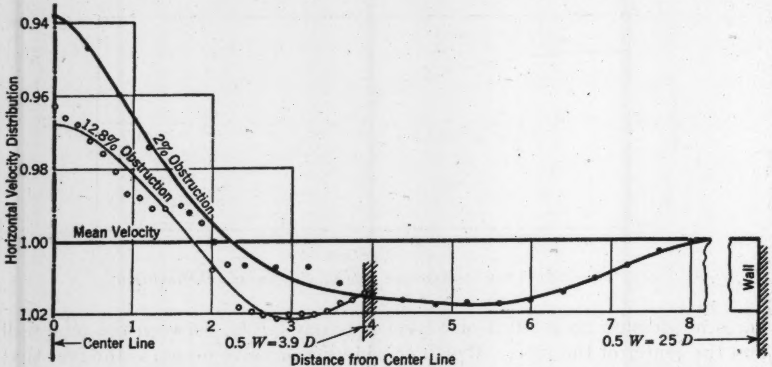

FIG. 39.—VELOCITY DISTRIBUTION VERSUS WIDTH IN THE PLANE OF THE STATIC OPENINGS

The foregoing phenomena make it almost impossible in a power installation to find a run of pipe in which it can be certain that only straight-pipe friction is reflected in differences in the readings of wall piezometers. For the present experiments, the most reliable result estimates of straight-pipe friction were obtained by utilizing the measurements made in the 13-ft turbine penstocks in connection with the Gibson (36) efficiency tests of the turbines. The measuring section F G of Fig. 35 included 8 diameters of pipe, located 8 diameters from the branch. The results, Fig. 40, at $\mathbf{R} = 20 \times 10^6$, gave a value of $f = 0.0207$. Utilizing the model tests, which showed that in such a location about 0.03 h_v of the measured drop should be ascribed to the upstream diversion loss, the friction coefficient for 13-ft diameter straight pipe was estimated at $f = 0.0177$, corresponding to Manning's $n = 0.015$, to Scobey's $K_s = 0.475$, and to Nikuradse's sand roughness factor $\frac{K}{\mathbf{R}} = 0.00134$. This latter factor can be interpreted as meaning that the bitumastic-covered surface of the 13-ft pipe was as rough hydraulically as if it had been coated with uniform sand grains 0.1 in. in diameter. According to the field observers, broom marks and joints were readily visible in the bitumen, a 20-ft straightedge showed $\frac{1}{8}$-in. openings below it, and flattened bolt heads projected $\frac{1}{8}$ in. from the welded interior of the pipe. Friction coefficients for other sizes of pipe were computed from these measurements, assuming them to vary inversely as $D^{1/3}$, the value for the 30-ft pipe being $f = 0.0134$. These unexpectedly high values can be compared with the results obtained from concrete pipe at comparable values of **R** plotted on the graph of Fig. 40. Also on the same graph are plotted overall losses per diameter for each of the sections measured—A D, A E, A H, etc. (see Fig. 35). Since the values are approximately constant at 0.03 h_v per

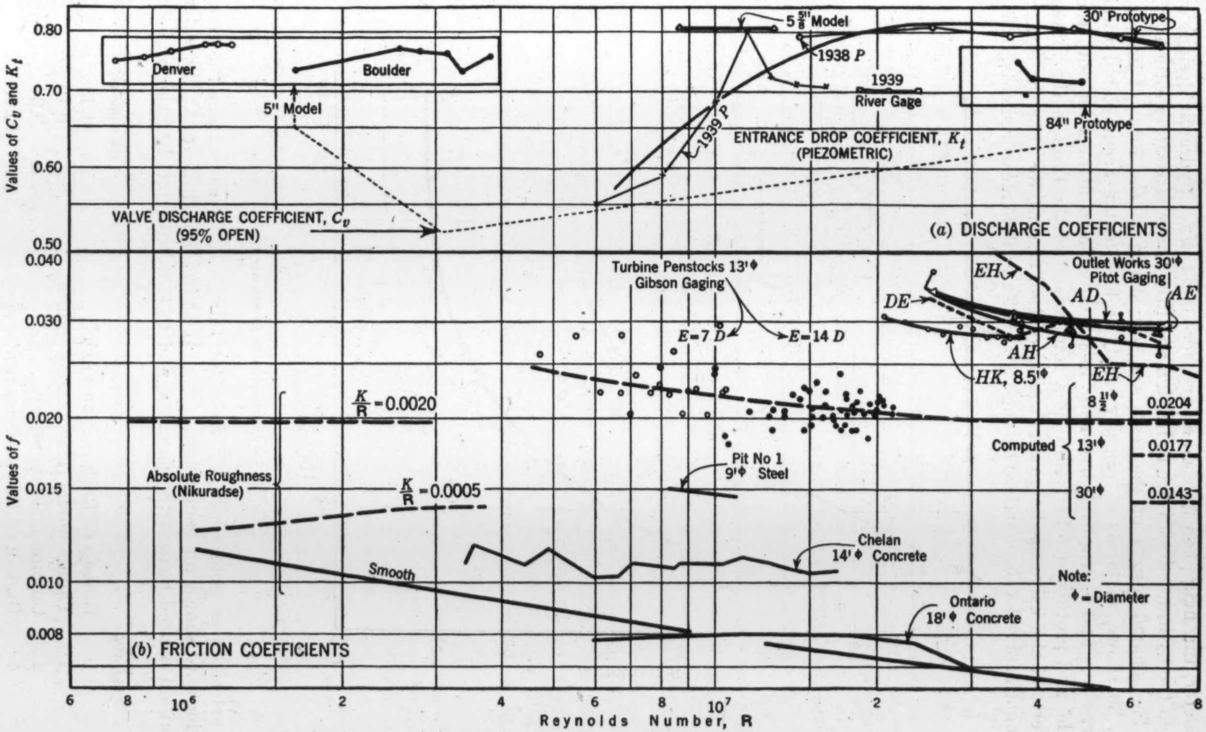

FIG. 40.—COMPARISON OF FRICTION FACTORS

diameter, this figure can be used as an over-all check for hydraulic designs in which the hydraulic losses due to friction and fittings are separately estimated.

The general results of the tests are best shown in the form of graphs. Fig. 36 shows, in terms of velocity head, profiles of the accumulated total energy loss and of the total hydraulic loss ascribable to fittings for both the model and prototype. Fig. 40(*a*) is a comparison of the drop in the intake tower and the valve discharge coefficients plotted against **R**. For the former a smooth curve has been passed through the 1939 and 1938 measurements, based on velocities as determined by the pitot tube. The results from the river gagings are shown for comparison. Fig. 41 shows branch losses at the valve manifold plotted against the percentage of total flow diverted to the branch:

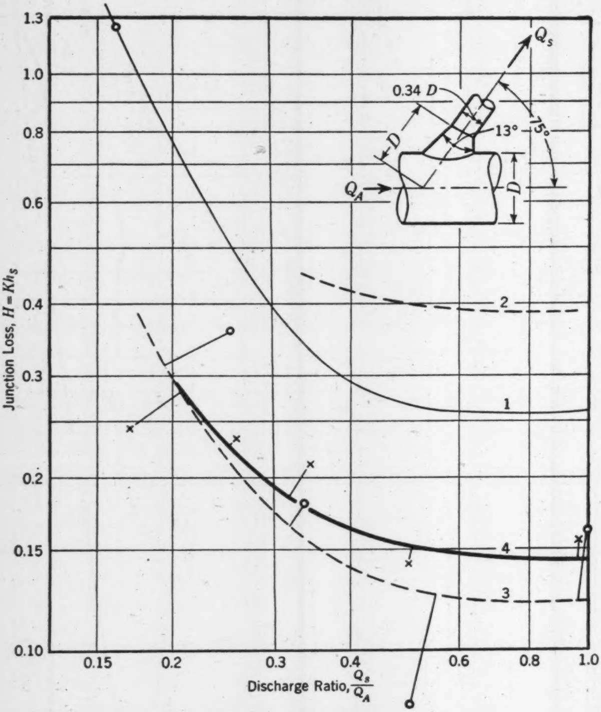

FIG. 41.—JUNCTION LOSS COEFFICIENTS

Curve (Fig. 41)	Structure	Reynolds' number (in millions)
1	Bureau of Reclamation model	0.05
2	Thoma model (interpolated values)	0.10
3	Commercial laboratory	0.30
4	Bureau of Reclamation prototype	40.00

Table 4 compares the various loss coefficients for the entire structure as originally estimated, as found from the model, and as estimated from the prototype tests.

Quantitative correspondence between model and prototype can be expected only where Reynolds' criteria can be satisfied and where absolute roughness in the model can be scaled down in accordance with model laws. This was not possible in the Boulder model which, while as smooth as possible, was materially rougher than demanded by similitude. Referring to the fitting loss of Fig. 36, it can be seen that in the prototype at point D, 23 diameters from the entrance, there was an indicated loss of about one half that measured in the model and at point H, 57 diameters downstream, a value 85% as large. It will be noted, moreover, that at point D the accumulated fitting loss in the prototype is shown as only one half that observed 20 diameters upstream immediately downstream from the intake. It will be realized at once that this decrease in accumulated loss downstream as measured by wall piezometers is due to the fact that the profiles are only nominal energy grades and include no corrections for actual velocity distributions. It appears probable from these tests that the prototype, with relatively less friction than the model, requires a greater length, measured in diameters, to regain its pressure head following the contraction below the intake. The required length may be analogous to the distance required to produce normal distribution below an intake in a smooth pipe, for which S. Goldstein (37) gives the formula

$$L = 0.7\, D\, \mathbf{R}^{0.25} \qquad (7)$$

Applied to the present tests, four times the length required in the model, measured in diameters, would be required to produce normal velocity distribution in the prototype. Whatever the reason, it is believed that the over-all measured prototype fitting loss, 0.85 h_v (which includes entrance, two bends, the disturbances caused by openings for four branches, together with their eight tie rods, and a 30 by 25 reducer), provides a satisfactory check on the model results. In Table 4 this over-all loss has been broken down into its

TABLE 4.—COMPARISON OF LOSS COEFFICIENTS

No.	Description	Loss Coefficient in Terms of Velocity Head of 30-Ft Diameter Pipe

components and compared with the standard loss coefficient originally used for the preliminary design of the outlet works[7a] and with those later obtained from the model. Although the breakdowns are only estimates based on a consideration of all the data, these fitting coefficients should be helpful to designers until better values become available. It is estimated that the values have a standard error of the order of 15%.

The entrance loss into the tower through its radial ports, 0.63 h_v as given from the foregoing breakdown, is sometimes confused with the piezometric drop which occurs from the lake to the water surface within the tower. The latter (as is shown in the bulletin[7a] (34) on the model tests) involves a reaction head due to the water turning downward within the tower and is not an absolute measure of entrance losses. This coefficient of tower drop, however, as obtained from various gagings, forms a good means of comparing performance of model and prototype. The results are shown in Fig. 40. Although at first sight the variations in the different tests may seem large, the 12% range in the experimental values is believed comparable to the precision of the majority of prototype tests. The increase in the coefficient with increasing **R**, as indicated by the curve averaging the 1939 and 1938 prototype results, may, perhaps, be partly accounted for by the formation of vortices at the intake which were observed in the 1938 measurements. At that time the head on the intake was only from four to six times the mean velocity head. Since the velocity heads for some of the stream filaments passing around certain unavoidable sharp edges of the intake, measured in terms of the mean velocity, may have been even a larger multiple of the mean head with the corresponding absolute pressures approaching zero, this is a condition which should be taken into account by designers, as the vacuum may cause cavitation and the entraining by vortices of large quantities of air. Without complete exploration of pressures in a model, it is a condition that is difficult to predict.

The model showed a loss through the screens of 0.10 h_v. In the prototype the loss was less than one tenth of this value. This undoubtedly was due to the fact that velocity through the model screens was below Reynolds' critical value. A model should not reproduce from the prototype details within which subcritical velocities may exist during the model tests.

Of considerable interest to designers is the loss due to a closely connected 90° vertical and 40° horizontal bend. Although the computed loss coefficient for the prototype of 0.08 h_v may have a considerable percentage error, the total measured loss for all the fittings was such that the bend loss, regardless of assumption, must have been small. To the writer's knowledge this is one of the few prototype tests that has been made on bends.

The junction loss for the branch from the manifold is shown in Fig. 41. Curve 1 for the model is interpolated from a very complete series of tests described in the bulletin[7a] (34). Curve 2 was likewise interpolated from D. Thoma's well-known tests (38). Curve 3 was obtained from the results of a commercial laboratory in connection with the design of the turbine manifold. It will be noted that the observations defining its averaging curve are widely scattered. Any one who has examined critically the technique by which fitting losses must be obtained, as set forth in the bulletin[7a] (34), will appreciate how difficult it is to obtain reliable results and will know that only in the exceptional test can the absolute values of the results be accepted. It is enough to state that coefficients of fitting loss are not fixed quantities depending merely on shape. They tend to decrease with increasing smoothness and with increase of Reynolds' number, and to be greater the greater the distance below the fitting at which they are measured. Also, it is to be noted that with multiple similar branches from a manifold, the loss will be different at each successive offtake due to change in the value of the percentage of the main flow diverted.

[7a] Boulder Dam.

The needle valve discharge coefficients are shown in Fig. 40. It will be noted that in the model with increasing **R** the coefficient increased, whereas in the prototype it decreased. The first case undoubtedly reflects the decrease in friction through the valve with increase in **R**. In the second case an analysis of the velocity distribution due to a curved streamline within the valve indicated the probability that at certain points vacuum was approached at high values of **R**. Once this point was reached, the effective area of the waterway would be reduced, cavitation would commence, and the discharge coefficient would decrease. The performance of the prototype was in line with these predictions.

It is believed that on the whole the use of a model for predicting quantitative results in the outlet works[7a] was pre-eminently successful, nearly halving the error in design that would have existed without its use. On the other hand, much more experimental data and development of theory are needed if predictions of losses within 10% are desired in the prototype. Particularly required are methods for forecasting pipe friction in terms of a quantitative pipe roughness and for estimating fitting losses at various distances downstream in the stretch before velocity distribution has become normal. Finally, it must not be forgotten that there is no way in which a factor of safety can be applied in the economic layout of the flow line of a hydroelectric development. An overestimate of hydraulic losses leads to the overdimensioning of the conduit with excess interest charges in perpetuity, whereas an underestimate leads to continuous waste of power in excess friction losses.

ACKNOWLEDGMENT

The field work was directed by John Parmekian and N. G. Noonan. Special appreciation is due R. E. Kennedy, M. Am. Soc. C. E., who made the computations.

[7a] Boulder Dam.

SPILLWAY COEFFICIENTS, NORRIS DAM

By G. H. Hickox,[8] M. Am. Soc. C. E.

Synopsis

The determination of discharge coefficients for the dam spillway crest gates[8a] is described in this paper. Actual coefficients calculated for the gates from records of their performance during the flood of January and February, 1937, are compared with the coefficients predicted from tests made on a 1 : 72 scale model by the Bureau of Reclamation. This comparison indicates that the coefficients predicted by the model average 3.9% larger than those actually measured on the dam during this period.

General Conditions

Norris Dam was built by the TVA as a part of its program of navigation, flood control, and power development of the Tennessee River Valley. It is situated on the Clinch River about 25 miles northwest of Knoxville, Tenn., and controls the discharge of 2,912 sq miles of land drained by the Clinch and Powell rivers.

It is a concrete gravity structure having a total length of 1,860 ft and a maximum height, to the roadway on the top at El. 1061, of 265 ft. The spillway crest is at El. 1020 and is 300 ft long, divided into three bays each 100 ft long. Three hydraulically operated steel drum gates are installed on the concrete spillway crest, and the crests of the gates may be raised to any elevation between 1020 and 1034 to retain flood peaks. Eight outlet conduits permit the discharge of water when the reservoir level is below the spillway crest. The maximum discharge of these conduits with reservoir level at El. 1020 is approximately 37,000 cu ft per sec. The power house contains two generating units, each having a capacity of 56,000 kva.

Fig. 42 shows a general plan and elevation of the dam and a section through the spillway. Fig. 43 gives the dimensions of the spillway crest in detail.

Flood of January, 1937.—Unusually heavy rains on the Ohio River drainage basin in December, 1936, and January, 1937, resulted in flood stages all along the Ohio River. During this period the entire flow of the Clinch and Powell rivers above Norris Dam was stored in Norris Lake. This necessitated raising the spillway drum gates to hold water a maximum of about 11 ft above the concrete spillway crest. Late in January it was seen that moderate discharges at Norris Dam would not cause further rises on the Ohio River, and accordingly water was released from Norris Lake to provide storage space for additional runoff. Much of the water was released by lowering the crest gates and allowing it to discharge over the spillway. Advantage was taken of this opportunity to obtain the necessary measurements for determining the discharge coefficients of the spillway for heads on the gates as great as 9.8 ft and for discharges as great as 30,000 cu ft per sec.

[8] Senior Hydr. Engr., TVA, Norris, Tenn.

[8a] Norris Dam.

DATA AVAILABLE

Gate Operating Records.—The program of water release at Norris Dam required the discharge to be held approximately constant for considerable periods of time. It was necessary to change the elevation of the crest gates, since the water level in the reservoir was changing. Accordingly, the gates were reset about every two hours. A complete record of the operation of the spillway crest gates, giving the time at which changes were made in the gate

settings and the elevations to which the gates were set, was available from the records kept at the power house. Records of reservoir water-surface elevations were also available.

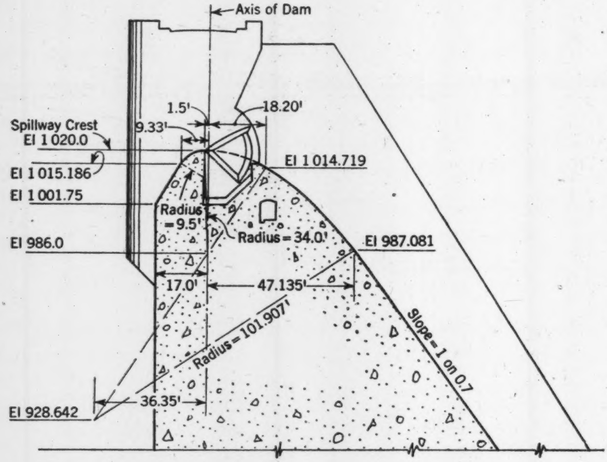

FIG. 43.—DIMENSIONS OF SPILLWAY CREST

Discharge Records.—A gaging station has been established by the U. S. Geological Survey at a point 0.9 mile below Norris Dam. A standard recorder was installed, and a continuous record for the period of spillway discharge was available. The rating curve is well defined since the control is a solid rock diagonal reef about 150 ft below the gage. A number of discharge measurements were made during the flood period. Only one of these is as much as 4% from a mean rating curve, and most of the measurements are less than 1% from the curve.

CALCULATION OF DISCHARGE COEFFICIENTS

Notation.—The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference under "Bibliography and Notation" at the end of the Symposium.

Correlating the Data.—In computing the discharge coefficients, it was necessary that the discharge over the spillway should be the same as that at the gaging station and that the river stage at the gaging station should be steady. As previously mentioned, the gates were adjusted about every two hours, causing fluctuations in the discharge. In most cases a 2-hr period was sufficient to allow the stage at the gage to become steady, since the changes in discharge were usually small. When observations were used which were only two hours apart, the elevations of the gate crest and the reservoir level were taken as of immediately before the change—that is, at the end of the 2-hr period. The gage height at the gaging station was also taken at the end of the period.

When large changes in discharge occurred, a greater time was required for the river stage to become steady. When it appeared from the recorder chart that a steady condition had not been established at the gage, the data were not used. No data were used to determine discharge coefficients if there was any doubt as to their value, either because of unsteady flow or for any other reason. Use of river discharge at the gaging station to represent the discharge over the spillway at the same time is justified because of the care in rejecting data which did not represent steady flow and because of the relatively small storage between the dam and the gaging station.

Table 5, Cols. 1 to 8, inclusive, lists the data regarding reservoir and gate-crest elevations obtained from the power-house records. Col. 9, Table 5, gives the gage height, in feet, at the gaging station, corrected from the continuous chart.

Calculation of Discharge.—A rating curve for the gaging station was constructed from the discharge measurements by plotting the discharges against gage heights and drawing a curve through them so as to give greatest weight to those measurements that were made during the period of observation.

There is practically no inflow to the river between the dam and the gaging station. The gaging station records indicate that, just before spillway discharge began, the combined inflow and leakage through the dam was about 50 cu ft per sec. Col. 10, Table 5, gives discharges taken from the rating curve, less 50 cu ft per sec for all discharges less than 10,000 cu ft per sec. For discharges greater than 10,000 cu ft per sec, the correction was neglected since it amounted to less than 0.5%. The discharges of Col. 10, determined as described, are considered to be the spillway discharges for the corresponding reservoir and gate-crest elevations of Cols. 3 to 7.

Calculation of Discharge Coefficient C.—The discharge coefficient, C, was computed by means of the customary weir equation,

$$Q = C\,b\,H^{1.5} \quad \text{.........................} (8)$$

in which: Q = discharge, in cubic feet per second; C = discharge coefficient; b = length of weir crest, in feet (for one dam, 300 ft); and H = head on weir crest, in feet.

Cols. 4, 5, and 6, Table 5, show that the crest gates were not all at the same elevation but varied somewhat, giving different heads on the gates. The discharge coefficient varies slightly with both the elevation of the gate crest and the head, but the variation is not perceptible for the differences observed. The maximum variation of head between gates is 5.7% for Observation No. 1. The results of the first six observations are quite widely scattered, and, if these are omitted from consideration, the maximum variation of head is 1.5% in Observation No. 7. Variation of the discharge coefficient due to this change in head may be neglected. A slight error is also introduced if the average head is used in the weir formula, but with a maximum head difference of 1.5%, this error also may be safely neglected. Col. 8, Table 5, gives the average head on the three gates for each observation. Values of C calculated from

the formula,

$$C = \frac{Q}{b\,H^{1.5}} \qquad (9)$$

are given in Col. 11.

COMPARISON WITH MODEL COEFFICIENTS

Determination of Model Discharge Coefficients.—Discharge coefficients for the dam spillway were measured by the Bureau of Reclamation on a 1 : 72 scale model (39). It was found that because of the shape of the drum-gate crest, which changed with the elevation of the gate, C, in Eq. 8 was neither a constant nor a function of the head. The Bureau found that the tests made on the model could be represented by the equation,

$$Q = K\,b\,H^{n} \qquad (10)$$

in which K and n are constants which vary only with the elevation of the gate crest. Values of K and n for each elevation of the drum-gate crest are given (39*a*) in Fig. 44.

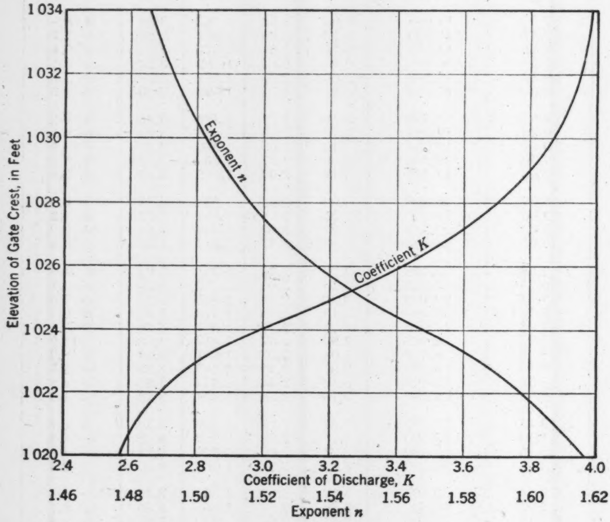

FIG. 44.—VALUES OF K AND n IN EQ. 10

To compare the model tests with the results of observations on the prototype, it was desirable that coefficients of discharge be expressed in the same terms for each. The data obtained on the prototype do not cover a sufficient range to permit the determination of K and n. However, values of C can be computed from the Bureau's tests. Equating the two expressions for Q, Eqs. 8 and 10,

$$K\,b\,H^{n} = C\,b\,H^{1.5} \qquad (11)$$

From this,

$$C = K\,H^{n-1.5} \qquad (12)$$

Values of K and n from Fig. 44 are given in Cols. 12 and 13 of Table 5, and the corresponding value of C, computed by Eq. 12, is given in Col. 14. This column has been headed C_m in order to distinguish the coefficients computed on the basis of the model tests from those determined on the prototype. Col. 15, Table 5, compares the two values of C by showing the percentage by which C_m is in error when compared to C.

A few of these values should not be used for drawing general conclusions. The first six observations are for relatively small discharges and low heads on the crest for which errors of observation cause large percentages of variation. Observations Nos. 37 to 39 give discharge coefficients for a single gate. They are probably correct but should not be compared with the coefficients determined for three gates, since the discharge over a single gate is subject to much greater end contractions. If these nine observations are eliminated, the average of the forty-eight remaining values is +3.9%, indicating that the model tests predicted discharges which average 3.9% greater than those actually obtained. The reason for this is not known, although it is possible that the model coefficients are not accurately known in this range. It is generally believed that, other things being equal, small-scale models will give discharge coefficients somewhat less than the prototype. There is no reason to discard any prototype observations other than those referred to, as all questionable observations were omitted before calculations were made. It is believed that the values of C determined for the prototype are reasonably accurate.

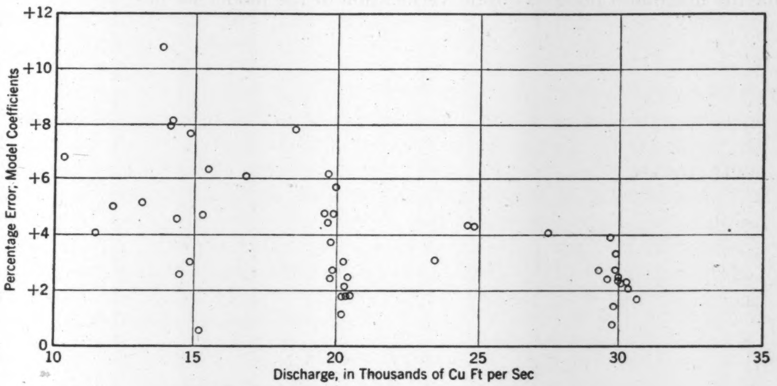

FIG. 45.—PERCENTAGE OF ERROR IN MODEL COEFFICIENTS

Fig. 45 shows the percentage difference of the forty-eight observations considered, plotted against the discharge. There is a definite tendency for the difference to decrease with increasing discharge. In this connection, it is interesting to note that, of the tests performed by the Bureau of Reclamation, only five actually fell within the range of operating conditions represented by the observations on the prototype. In other words, the model discharge coefficients for this range have been determined largely by extrapolation. As the region of more model data is approached, the difference becomes less. It is possible that the difference may decrease still further for higher discharges. Observations for discharges in the range of 60,000 to 100,000 cu ft per sec will be necessary before a more definite comparison of the model and its prototype can be made.

CONCLUSION

The comparison shows that model tests may be relied on to predict prototype discharge coefficients with an accuracy at least equal to that of streamflow measurements. The average discrepancy of 3.9% is not serious and is certainly less than might be expected without the benefit of model tests. It is quite possible that this difference might have been much less if the measurements on the prototype had been made in a range of discharges that were more adequately covered by model tests. This seems to be indicated by the trend of Fig. 45.

Accurate quantitative comparisons of model and prototype discharge coefficients are scarce because the model tests are generally made in the region of maximum discharge which seldom, if ever, occurs in the prototype. Many more comparisons could be made if the model were tested not only for the maximum discharge but also for the smaller discharges that occur more often. It is suggested that future tests on spillway coefficients be made to include the range of frequent prototype operation so that it will not be necessary to wait for the maximum flood to obtain verification of the model studies.

PRESSURE HEADS ON BONNEVILLE DAM

BY J. C. STEVENS,[9] M. AM. SOC. C. E., AND R. B. COCHRANE,[10]
ASSOC. M. AM. SOC. C. E.

SYNOPSIS

The main hydraulic features pertaining to the design of Bonneville Dam, in Washington and Oregon, were studied by models in the Bonneville Hydraulic Laboratory. (This laboratory was located at Government Moorings near Linnton, within the City of Portland, Ore., from December, 1933, to January, 1937; hence, it is sometimes called the Linnton Hydraulic Laboratory. It was later moved to the Bonneville Dam site.) Among these features were the hydraulic characteristics of the 50-ft by 50-ft crest gates with water flowing beneath them (40), and the hydraulic effect of departures of the profile of the constructed dam from the design profile. During the latter studies the pressures on the model crest were determined for various gate openings.

A series of piezometer taps constructed in the crest of the prototype dam, corresponding to those in the model, were used to observe pressures on the crest for various gate openings.

This paper presents the results of the pressure-head profiles on the underface of the overflowing nappe in both model and prototype. When the gate was in the downstream position, the pressure profiles of model and prototype checked fairly well; when the gate was in the upstream position, however, anomalies developed that may serve as the subject for some interesting speculations.

THE MODEL

A replica of a 10-ft length of the crest and gate was made to a scale of 1 : 5 in a flume 2 ft wide, 10 ft deep, and 10 ft long (Fig. 46). In the prototype piers there are two gate grooves; in one the gate seal is 9 ft upstream from the center line of the crest and in the other it is 8 ft downstream. To simulate these positions the entire model crest block could be shifted to either position. The gate was held by stay rods so that it moved parallel to itself, and the rods were so long that this movement virtually simulated the prototype. The effect of the gate grooves was absent in the model, watertightness being secured by stanching strips of rubber.

MODEL TESTS

The model tests were made primarily to determine the effect of slight departures of the constructed crest from the design crest, and to establish the tolerances that might be permitted in the crest and ogee profile. These experiments consisted essentially of observing pressures at the contact surface between the concrete crest and the overflowing nappe. Three distorted crests were studied for gate openings of 0.25, 0.5, 1.0, 2.0, and 3.0 ft with the gate in both the upstream and the downstream positions. Fig. 47 shows the design crest and the three types of distortions used in the experiments.

In addition to tests on the 1 : 5 model, pressure on the crest was observed for a large range of gate openings in the middle one of three bays of a 1 : 36 model. The gate was in the downstream position only, and the piezometer taps were at 5-ft intervals downstream from the center line of the crest. Since the prototype gate openings were 4 ft and less, comparisons up to that value only could be made.

Prototype Tests

Prototype tests were made in Bay No. 13 of the completed dam in October, 1939. The crest profile in this bay was without appreciable departure from the design crest. The piezometer taps were spaced to conform to those of the 1 : 5 model except that in the prototype, Piezometer No. 1, 4 ft upstream from the axis, was substituted for model Piezometer No. 8, 9.58 ft upstream from the axis. The prototype also had, in addition to those in the model, Piezometers Nos. 10 and 12 located 27.5 ft and 42.5 ft downstream from the axis.

The piezometer taps were made in a steel plate 10 in. wide set flush with the concrete and bent to the shape of the design crest. From each tap a ½-in. iron pipe led through a stopcock to a manifold in an inspection gallery in the dam. A 60-lb Bourdon pressure gage, reading positive pressures above atmospheric, was connected to the manifold at El. −28.89 ft, so that the pressure at each piezometer could be read in turn.

FIG. 47.—CREST PROFILES, MODEL OF BONNEVILLE DAM

Two series of tests were made, one with the gate in the downstream groove —its normal position—and the other in the upstream groove—an emergency position. In addition to observing the pressures at the underface of the nappe, the surface profile of the nappe was obtained for a distance of 24.5 ft downstream from the gate seal when in its downstream position and 13 ft downstream from the gate seal when in its upstream position.

The surface profile for a length of 16 ft near the crest was also obtained for "gate removed," when the crest was under a head of 47.8 ft. There are no facilities for measuring the flow through any one bay, but tests on the 1 : 36 model indicate that under that head this 50-ft bay was discharging about 62,000 cu ft per sec or 1,240 cu ft sec per ft of crest.

The surface profiles (see Table 6) were obtained by means of a steel plate 48 in. by 48 in. by 1½ in., weighing about 1,000 lb, handled by the auxiliary hoist on the gantry crane which could be moved perpendicular to the axis of the dam. There is much spray from the gate groove in the piers (see Fig. 48) beneath the gate which, however, did not affect the position of the steel plate; but when the corner of the plate touched the solid nappe the plate was kicked violently downstream.

During these tests the tailwater level was 12 ft so that the crest was not submerged.

COMPARATIVE RESULTS

The results of the tests on models and prototype are presented in Table 7, other data for a 2-ft gate opening being plotted in Fig. 49. Observations on the 1 : 36 scale model, shown in Fig. 49, were also made for gate openings of 1, 3, and 4 ft. For gate openings of 0.25 and 0.5 ft the comparison was between the prototype and 1 : 5 model only (see Table 7).

The pressure heads on both model and prototype are in fair agreement for the gate in the downstream position. The maximum negative pressure head observed in the prototype was −1.2 ft for a gate opening of 1 ft at Piezometer No. 6, just below the gate seal. The greatest negative heads in either model had about the same values at approximately the same localities.

For the gate in the upstream position there are some interesting departures of the prototype pressure heads from those of the model. Table 7(*b*) shows the comparative pressure heads (see also Fig. 49(*b*), for a 2-ft opening). Unfortunately, prototype Piezometers Nos. 3 and 8 were clogged. Every effort to free them with compressed air failed.

If the prototype pressure heads for Piezometer No. 3 could have been taken for gate openings of 0.25 and 0.5 ft, one might assume that conformity could have been demonstrated, but one dares not go any farther with that assumption. For gate openings of 1, 2, and 3 ft, the anomalies between prototype piezometer heads Nos. 2 and 3, and the corresponding model piezometer heads Nos. 4 and 9, became increasingly obvious.

In drawing the line of prototype pressure heads between Piezometers Nos. 7 and 9 for the five gate openings, one might have "upped" the curve to conform to the line obtained in the model, but without the model results the prototype line would not have been so drawn. Moreover, to have drawn it otherwise than indicated in the example (Fig. 49), particularly for the gate openings of 3 and 4 ft, would have made it a rather "goofy" curve.

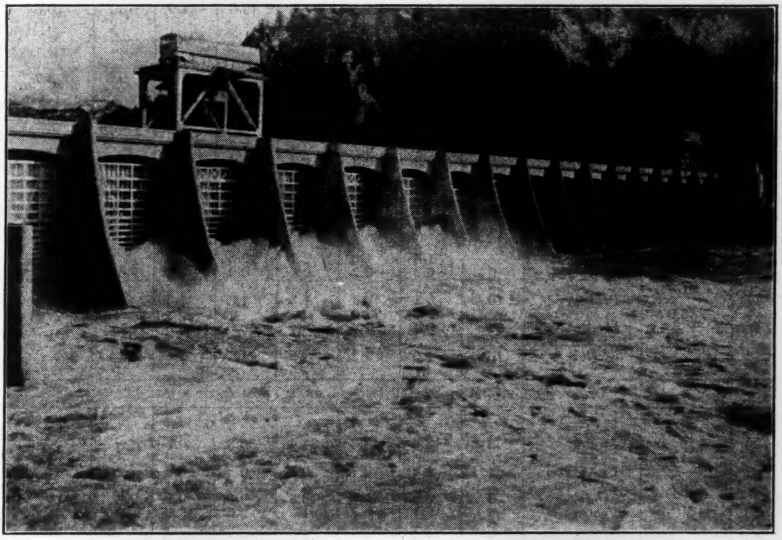

FIG. 48.—VIEW OF BONNEVILLE DAM SHOWING SPRAY FROM GATE GROOVE IN PIERS

The explanation for the discordant results undoubtedly lies in the fact that with the gate in the upstream position there is a tendency for the jet to spring free from the crest. This tendency creates a zone of subatmospheric pressure just beyond the axis or crest of the spillway. The maximum observed negative pressure head in the prototype in this zone is -5.0 ft at Piezometer No. 4 (Table 7(*b*), item 26), whereas the projected pressure head at Piezometer No. 3 (Fig. 49) might have reached -6.0 ft.

These negative pressure heads appear to reach a maximum about 5 ft beyond the crest and gradually diminish to positive pressures about 15 ft beyond the crest (see Table 7(*b*), 4-ft opening). This effect doubtless would become more marked and reach a maximum at some larger gate opening, and thereafter gradually diminish, as evidenced in the last column of Table 7 where all pressure heads are definitely positive. For the prototype this is a

perfectly normal behavior, and the line of pressure heads is believed to represent the true state of affairs. Why, though, did not the model experiments disclose the same tendency? All model pressure heads with the gate in the upstream position are on the positive side.

To show these anomalies better, Table 8 has been prepared. It gives the difference in pressure heads between prototype and model downstream from the crest for the gate in the upstream position. Nearly all differences are negative; that is, the prototype pressure heads are lower than the model pressure heads, and these differences increase as the gate openings become larger.

[a] Distance from axis of dam to piezometer, in feet.

Fig. 47 shows that model tests G-6 were made with an undistorted crest, while tests G-4, G-5, and G-7 were with distorted crests. The depressions in the concrete crest, however, begin at the downstream gate seal, which is 8 ft below the axis except for G-7 for which crest was raised between the gate seal and the axis. Anomalous pressure heads shown in Table 7(*b*) appear upstream of these crest distortions; hence, these distortions cannot be assigned as the cause of the discrepancies.

The negative pressures resulting from the nappe adhering to the underface of the gate below the seal (40) obviously cannot be assigned as a cause of the departure of the model from prototype behavior for two principal reasons: First, the anomalies occur far downstream from the gate and, second, the underface of both the model and the prototype gate was perforated to admit air. The perforations on the prototype gate consist of three rows of staggered $1\frac{1}{16}$-in.

holes, so spaced as to be the equivalent to a continuous $\frac{7}{8}$-in. slot parallel to the rubber seal strip and communicating with the atmosphere on the downstream side of the gate. The first row of holes is 5 in. downstream from the center line of the seal strip. The perforations through the underface of the 1 : 5 model gate simulated those of the prototype as nearly as was practicable.

CONCLUSIONS

The writers can offer no valid explanation for the anomalous results between model and prototype with the gate in the upstream position.

Under such high velocities—45 ft per sec for the prototype and 20 ft per sec for the model—the difficulty of obtaining accurate pressure heads through piezometers was fully recognized and every precaution was taken to eliminate such sources of error. The departures from conformity are not of this nature. The model consistently refused to show negative pressures where such pressures should have obtained just below the crest.

METER MEASUREMENTS OF DISCHARGE, UNIVERSITY DAM

By Edward Soucek,[11] Assoc. M. Am. Soc. C. E.

Synopsis

A comparison between a series of current-meter measurements of discharge over a dam on a midwestern river[11a] and tests of a 1 : 12 scale model of a section of the dam is presented in this paper. Prototype heads covered by the measurements ranged from 1.7 to 6.3 ft, and discharges ranged from less than 2,000 to nearly 16,000 cu ft per sec. Eleven of the twenty-three discharge measurements were made while the dam was submerged. Submergences ranged from less than 12% to nearly 90%.

Model discharges averaged approximately 5% less than comparable discharges obtained for the prototype. The comparison would appear somewhat more favorable if made in terms of head. It is by no means certain that the discrepancy is chargeable to the model.

Both model and prototype exhibit a considerably smaller diminution of discharge capacity, due to submergence, than was anticipated. The model tests demonstrate the inadequacy of single-valued relations between submergence and reduction in discharge capacity. Observations on the behavior of the nappe are presented.

Introduction

Submerged flow, defined as the condition that exists when the tailwater at a dam is at an elevation greater than that of the crest, often occurs during floods at low-head dams. Dams designed to remain submerged at all times are used to increase depths in lakes and rivers. Despite the considerable importance of the problem, published data on submerged flow over dams are exceedingly rare. The writer knows of no previous model-prototype comparison involving this phenomenon. These facts motivated the investigation described in this paper.

Prototype

Measurement of the dam at five cross sections revealed that it was built to close agreement with construction drawings. The river bottom upstream from the dam, although somewhat variable transversely, can be represented fairly well by the broken line in Fig. 50. The dam is founded on rock which, at the toe, has been excavated and scoured to a maximum depth approximately 20 ft lower than the crest.

The spillway is 273.50 ft long, composed of a main section 269.50 ft long and a section 4.00 ft long apparently intended for use as a fishway. These sections are separated by a wall 1.48 ft wide that has its top 1.41 ft higher than the spillway crest. In profile, the top of the dividing wall roughly parallels the spillway. The wall is subject to overflow when the head on the dam exceeds 1.41 ft. An additional length of 6.75 ft is subject to overflow when the head exceeds 3.10 ft on the spillway proper. This additional length is a flat-crest section, 2.00 ft wide, at one end of the dam.

---

[11] Senior Civ. Engr., U. S. Engr. Office, Wilmington, N. C.

[11a] University Dam on the Iowa River at Iowa City, Iowa.

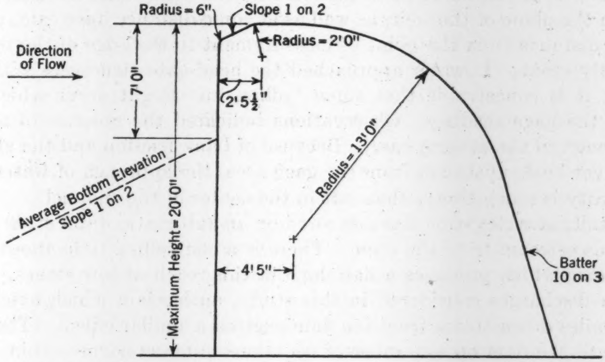

FIG. 50.—SPILLWAY CROSS SECTION, UNIVERSITY DAM

In comparing discharges of model and prototype, the measured prototype discharge was reduced by the estimated flow over the odd sections—namely, the dividing wall and the flat crest. Owing to the short length of overflow for the wall section and the low head on the high flat-crest sections, these corrections were small, never exceeding 1% of the measured discharge. Since any reasonable weir coefficient used in making the adjustment would give substantially the same results, the computation is not explained in detail, but both measured and corrected discharges are given.

The laboratory head-gate structures act as a non-overflow section of the dam 30 ft long. The gate pier adjacent to the spillway is well rounded, and no contraction of the nappe can be observed at the laboratory end of the dam. The power house forms a short non-overflow section of the other end of the dam. The intake crib, trashracks of which are parallel to the river bank, tends to reduce end contraction here also. Since even the Francis correction for a full contraction would have reduced the effective length of the spillway by only about 0.2% at the maximum head observed, no adjustment for end effects was considered necessary.

All data pertaining to the prototype are based on field measurements made during the course of the study.

OBSERVATIONS ON PROTOTYPE

The head on the dam was read on a staff gage mounted on a retaining wall on the laboratory bank of the river. The gage is only 6 ft upstream from a line projected along the spillway crest, but its sheltered position, 30 ft transversely from the overflow section, appears to keep the readings from being affected by drop-down. Some concern was felt over this apparently unfavorable location, but simultaneous observations of the water surface with a surveyor's level at the gage and at points clearly beyond any possible drop-down effect indicated that the location was satisfactory. The situation seems somewhat analogous to the measurement of head for a contracted weir in the side of a tank. There seems to be no reason why the head could not be measured nearly in the plane of the weir, as well as at some distance upstream, provided that the distance from the point of measurement to the edge of the weir were sufficiently great. If water approached the head-gate structures with a high velocity, it is conceivable that some "piling up" might occur which would increase the gage reading. Observations indicated the absence of any such phenomenon in the present case. Because of bank friction and the alinement of the river bank upstream from the gage area, the approach of water toward this vicinity is much slower than out in the center of the channel.

The tailwater elevation was measured by an automatic water stage recorder 350 ft downstream from the dam. There is a controlling riffle about 1,200 ft downstream which produces a flat slope in this reach at low stages. During the high discharges considered in this study, an ice jam which extended for several miles downstream from the dam exerted a similar effect. The ice jam built up to the dam on a number of occasions but was never within 500 ft of the dam during any of the measurements. These data on downstream conditions are cited because it is desired to show that the tailwater level would have been affected very little by changing the measuring point, provided that the point was clearly beyond the immediate effects of the dam, as was the case.

Discharge measurements were made from a cable station 470 ft downstream from the dam. Price current meters in good condition were used. Twenty of the measurements were taken by the 0.2 and 0.8 depth method. The remaining three were based on surface velocity alone. For these, a reduction coefficient of 0.9 was applied to determine the mean velocity in the vertical. (Some of the measurements made during the course of the study were used in making up the station record during the period of ice effect.) With due regard for the difficulty of making accurate measurements under adverse conditions, the measurements are considered reliable. A number of attempted measurements had to be abandoned because of floating ice.

MODEL TESTS

The model was a 1 : 12 scale replica of the cross section of the prototype but did not reproduce the structure as regards length, end effects, or bottom irregularities. The model was made by stretching a galvanized iron skin plate tightly over a welded steel frame. The surface presented to the flowing water was very smooth.

The model was operated in a glass-sided steel flume 26 ft long, 2.5 ft deep, and 2.56 ft wide, glass to glass. The model was bolted to the floor of the flume 15 ft from its downstream end. End seals were of pitch and marine putty, smoothed to the profile of the model. Bottom seals were of portland cement mortar. The silt against the upstream side of the prototype was simulated by an inclined plane of wood. Wooden baffles upstream from the model were used to produce uniform approach conditions.

Water was supplied to the flume at constant rates from the laboratory circulating system and was measured on a sharp-crested, fully suppressed and aerated, rectangular weir 2.51 ft long and 1.29 ft high. To insure an accurate rating, the weir was calibrated in place. This was considered especially necessary in view of the high discharges which taxed the capacity of the weir. A larger weir would have been preferable. For the calibration, a by-pass flume leading to a 20,000-lb capacity weighing tank was installed. An attempt was made to keep the condition of the weir crest the same during the model tests as during the calibration.

Prior to the tests, it was determined that the friction slope in the flume at the depths and discharges which were to be used would not exceed approximately 0.0001. Accordingly, the effect of friction in the flume could be neglected. This made it unnecessary to attain exact correspondence of points at which heads were measured on model and prototype, again provided that measurements were beyond the immediate effects of the dam. The head was measured 3.1 ft upstream from the back of the dam and the tailwater elevation 11.3 ft downstream from the same point. These points were determined experimentally as being out of the drop-down curve and beyond the rising and irregular water surface downstream from the dam, respectively. Both water levels were observed with point gages of the rack and pinion type mounted along the center line of the flume.

The discharge over the model was controlled with a gate valve in a 10-in. supply line leading to the weir tank. The tailwater elevation was regulated with a hinged flap gate at the downstream end of the flume.

NOTATION

The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference under "Bibliography and Notation" at the end of the Symposium.

RESULTS OF MODEL TESTS

Fig. 51 shows the relation observed for unsubmerged or free discharge between the coefficient C and the energy head for the model in the formula:

$$Q = C\,L\left(H + \frac{V^2}{2\,g}\right)^{1.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

In this weir formula: Q is the time rate of discharge, in cubic feet per second; C is a coefficient, dimensionally the square root of an acceleration; L is the length of a weir or dam crest, in feet; H is the measured head on a dam, referred to the elevation of the crest, in feet; V = average velocity of flow; and g = acceleration due to gravity. The head corresponding to the average velocity of approach, in feet, is expressed as $\frac{V^2}{2\,g}$.

Eq. 13 is used to characterize the flow whether free or submerged. The ratio of the discharge which occurs when the flow is submerged to that which would occur under the same energy head for free flow conditions is used as a measure of the diminution of the discharge capacity caused by submergence.

The results of model tests for submerged conditions are shown in Fig. 52. Following usual practice, the diminution in discharge capacity due to submergence is indicated by curves in which the submerged discharge, expressed as a percentage of the unsubmerged discharge which would obtain under the same energy head, is plotted against the submergence. For submergences lower than 45%, the relation between discharge and energy head was not affected by the submergence so the curves are not carried below a 45% submergence. The total model discharge and the discharge per foot of crest length are both given on these curves, the latter item being more significant since the length of the model bears only an incidental relation to the length of the prototype.

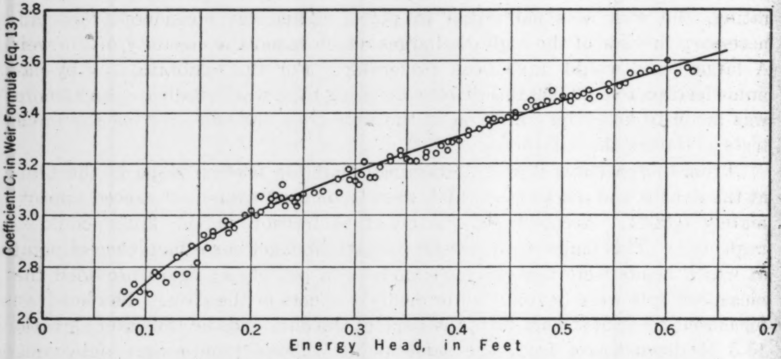

FIG. 51.—HEAD-COEFFICIENT RELATION FOR A MODEL WHEN NOT SUBMERGED

In Fig. 53, the curves of Fig. 52 are compared to a larger scale. An interesting relation exists between the curves for the five higher discharges. Given any two of the curves, or one curve and a well-defined point on another, the remaining three or four curves could be fixed by linear interpolation or extrapolation in terms of the discharge along the scale of relative discharges. Perhaps a slightly better fit to the plotted points in Fig. 52 could have been obtained if the curves had been drawn without regard for this property. It is seen that the curve for the lowest discharge does not correspond to the other five. The energy head for this discharge is less than 0.1 ft on the model. The matter is of great interest in connection with model-prototype relations at low heads because there is some question as to the behavior of the prototype for a corresponding discharge. It is regretted that this question could not be thoroughly investigated.

When water flows over a submerged spillway, the nappe may either plunge downward along the face of the spillway (as when the flow is unsubmerged) or it may flow away from the dam at or near the surface of the tailwater. The flowing nappe condition might be further subdivided according to the

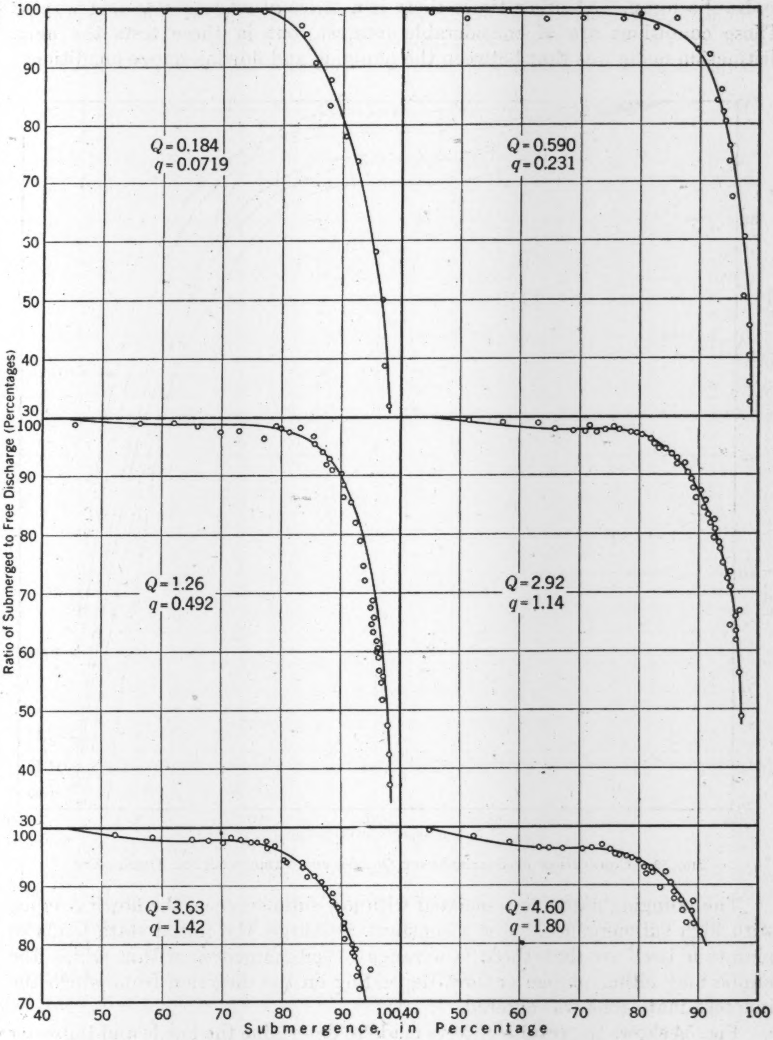

FIG. 52.—EFFECT OF SUBMERGENCE UPON MODEL DISCHARGE

appearance of the surface. Sometimes the surface has the appearance of a hydraulic jump. At other times there is a series of smooth standing waves. These conditions are of considerable interest, but in these tests the only distinction made was that between the plunging and flowing nappe conditions.

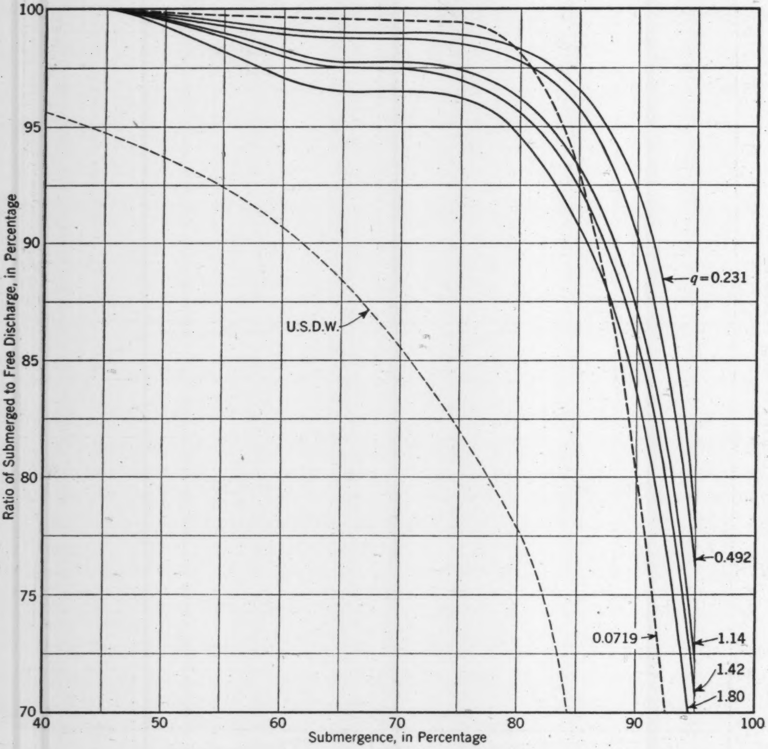

Fig. 53.—Comparison of Submergence Curves for Various Model Discharges

The plunging nappe is associated with low submergence, the flowing nappe with high submergence. For a constant discharge, the initial state tends to maintain itself so that there is a range of submergences within which the nappe may either plunge or flow, depending on the direction from which the indeterminate zone was entered.

Fig. 54 shows the results of tests made to determine the heads and tailwater elevations at which the changes from one nappe condition to the other occurred. The observational error was unavoidably high in making this determination. The results are self-explanatory. The lines drawn are not intended to represent the points but merely to give a better idea of the submergences at which these changes occurred.

Special tests were conducted to determine whether or not the behavior of the nappe had to be considered in studying the effect of submergence upon the discharge. This was done by manipulating the tailwater so as to create alternately plunging and flowing nappes for the same submergence and discharge. The nappe condition had no apparent effect on the relation between submergence and discharge.

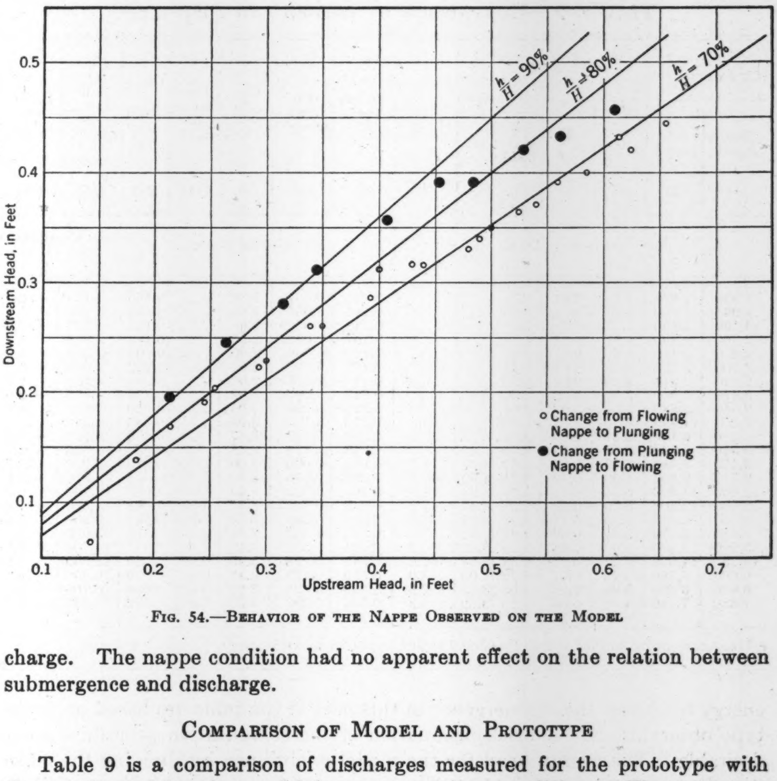

FIG. 54.—BEHAVIOR OF THE NAPPE OBSERVED ON THE MODEL

COMPARISON OF MODEL AND PROTOTYPE

Table 9 is a comparison of discharges measured for the prototype with those indicated by the model for corresponding conditions. The prototype measurements are arranged in ascending order of the discharge for free flow observations and in ascending order of the submergence for the submerged observations. The comparison could be made in various ways, the method adopted being one which gives the result in terms of discharge.

As previously explained, the length of the prototype spillway is 273.50 ft. A model 22.8 ft long $\left(\frac{273.50}{12}\right)$ would have been necessary to simulate the prototype as regards length. The model discharges per foot of length, therefore, must be multiplied by 22.8 as a length adjustment before being "scaled up" by Froude's law.

Table 9(*a*) gives prototype data which appear to require no explanation. Since model and prototype data are separated in the table, no subscripts are necessary to differentiate between them. Table 9(*b*) gives steps in the determination of the spillway discharge indicated by the model. Only the energy head and the submergence in this part of the table are based on prototype observations. A brief explanation of the computation procedure seems desirable. The energy head for the model is obtained by dividing the corresponding prototype item by 12. The submergence, being a ratio, is numerically equal for model and prototype.

[a] Measurement by surface velocity with 0.9 reduction; other measurements, 0.2 and 0.8 depth.

For free flow, or when the submergence is less than 45% (below which value the model indicated that submergence had no effect), q, the discharge per foot length of the model, is computed from the formula,

$$q = \frac{Q}{L} = C\left(H + \frac{V^2}{2g}\right)^{1.5} \qquad (14)$$

the coefficient being taken from the curve of Fig. 51.

When the submergence exceeds 45%, the discharge computed by Eq. 14 must be reduced by the curves of Fig. 53. The model shows, however, that the ratio of submerged to free discharge at the same energy head (hereinafter called simply the "discharge ratio") is a function not only of the submergence but also of the discharge, which is as yet unknown. Accordingly, the final value of the discharge ratio cannot be found until the discharge is known and vice versa. A solution can be found by a few easy approximations.

A simple procedure is to assume that the discharge ratio has the value of 100%. A first trial value of q can now be found, and a second trial value of the discharge ratio can be read from Fig. 53 by interpolation. This gives a second trial value of q. The process is repeated until q remains unchanged by further approximation, which it will after a very few trials. Obviously, the procedure can be shortened if a close estimate of either q or the discharge ratio is made initially. No trial computations are shown in Table 9, but the correctness of the results can be verified without approximation. An easier method of calculation could be derived if a large number of discharges were to be determined.

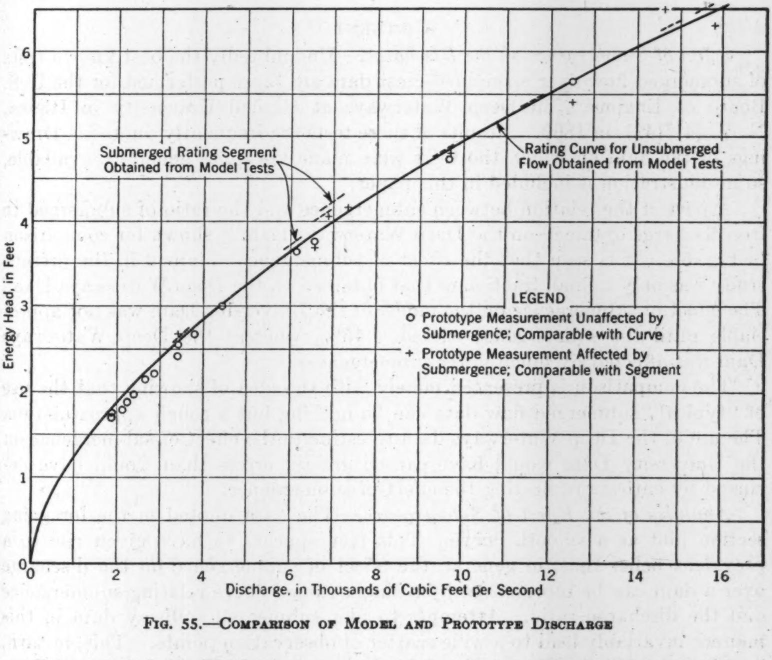

FIG. 55.—COMPARISON OF MODEL AND PROTOTYPE DISCHARGE

Cols. 13 and 14, Table 9, are comparative data. The spillway discharge indicated by the model is the product of three factors—the discharge per foot of length of the model, the length adjustment as previously explained, and the five-halves power of the scale ratio. Col. 14, Table 9, gives the percentage difference between the measured net spillway discharges and the spillway discharges indicated by the model for corresponding energy heads and submergences. The difference is considered negative when the indicated discharge is less than the measured discharge.

In Fig. 55 the performance of the model is compared graphically with prototype measurements. The continuous curve is an energy-head-discharge relation for free flow over the spillway, established from the model tests. Observations on the prototype when unsubmerged, or when the submergence did not exceed 45%, are comparable directly with this curve.

To avoid confusing the diagram, continuous curves were not drawn for submerged flow. For each submergence at which a measurement was made, a short segment of the submerged rating indicated by the model tests was drawn at the corresponding energy head. Since submergence reduces the discharge for a given energy head, the submerged rating segments all lie above and to the left of the curve for free flow. It should be noticed that the three measurements which show the greatest discrepancies are based only on surface velocity. No close agreement can be expected for these three measurements.

COMMENT

Effect of Submergence on the Discharge.—Undoubtedly the best known tests of submerged flow over a rounded-crest dam are those performed for the U. S. Board of Engineers on Deep Waterways at Cornell University in Ithaca, N. Y. (41)(42), in 1899. Results of these tests are frequently quoted. Drawings of the dam on which the tests were made are quite generally available, so no illustration is included in this paper.

A part of the relation between submergence and the ratio of submerged to free discharge obtained on the Deep Waterways Dam is shown for comparison in Fig. 53. It is seen that the effect of submergence obtained in the present study was only a small fraction of that obtained on the Deep Waterways Dam. The effect of submergence on the model of the University Dam was not appreciable until the submergence exceeded 45%, whereas the Deep Waterways Dam was affected by much lower submergences.

The comparison is presented merely with the idea of showing that the use of "typical" submerged flow data can be nothing but a rough approximation. The use of the Deep Waterways data to estimate the effect of submergence on the University Dam would have caused greater errors than would have occurred by entirely neglecting the effect of submergence.

Analysis of the Effect of Submergence.—The data quoted in the foregoing section plot as a smooth curve. This fact appears to have given rise to a prevalent belief that, in general, the effect of submergence on the discharge over a dam can be represented by a single-valued curve relating submergence and the discharge ratio. Attempts to plot submerged spillway data in this manner invariably lead to a wide scatter of observation points. This, in turn, leads to the opinion that submerged flow over dams is a far more unstable phenomenon than is really the case. The submerged flow tests of the first dam[11b] were made at a constant head of 6.6 ft. This made the tailwater elevation and the submergence functions of the discharge, which had to be decreased as the tailwater was raised to keep the measured head constant. Study of

---

[11b] Deep Waterways Dam.

Fig. 53 shows that, if a set of observations were plotted, in which the submergence was functionally related to the discharge, a single curve rather than a family of curves would express the results adequately.

If a stable control exists downstream from a dam, the submergence will indeed be related to the discharge in this special way. If model tests are made for such a case, the tailwater must be regulated to represent the prototype condition if a single-valued relation between submergence and its effect on the discharge is desired. This procedure is not recommended. If unwilling to vary the tailwater independently of the discharge as a matter of curiosity, the experimenter should consider the possibility that the control might change and invalidate the results if these results were so restricted in scope. The ice effect which caused the unusual degree of submergence observed in this study is a pertinent example.

Measurement of Tailwater Elevation.—The Society's *Manual of Engineering Practice No. 11*, entitled "Letter Symbols and Glossary for Hydraulics," defines submergence as follows:

> "The ratio of the tail-water elevation to the head-water elevation, when both are higher than the crest, the overflow crest of the structure being the datum of reference. The distances up stream or down stream from the crest at which head-water and tail-water elevations are measured are important, but have not been standardized."

In connection with measurement of headwater elevation, there seems to be no reason for departing from the procedure commonly used for unsubmerged weirs and dams—namely, the measurement at a point sufficiently distant from the overflow to be safely out of the drop-down curve.

G. N. Cox, M. Am. Soc. C. E. (45), measured tailwater elevation very near the dam. At this point, especially when the nappe plunges, there is a decided depression in the water surface. Even for the flowing nappe condition, the water level near the dam is at a lower elevation than farther downstream. The reason for a negative slope in this reach is a readjustment of velocity distribution which has an effect that is similar, as regards energy transfer, to the recovery of pressure head which occurs in the diffusing cone of a venturi meter. The investigation by Professor Cox dealt primarily with the use of the submerged weir as a measuring device. For this purpose, the use of a tailwater measuring point very near the dam is apparently satisfactory.

For most purposes, however, it is believed that a tailwater measuring point clearly beyond the rising water surface is decidedly preferable. Professor Cox found it necessary to consider the behavior of the nappe and gave a different formula for each condition. This is a complication that should be avoided if possible. If recording gages are used, the behavior of the nappe cannot be determined definitely from gage readings alone if the submergence is in the critical zone. At times during observations on the second dam,[11a] a plunging nappe existed over part of the spillway length and a flowing nappe over the remainder.

The model tests indicated that, if the tailwater level is measured at a sufficient distance from the dam, the behavior of the nappe need not be considered. This is just another way of stating that the over-all loss of head in flow over the model did not depend to any measurable extent on the behavior of the nappe.

[11a] University Dam.

It seems best, also, to consider the rising water surface downstream from the dam as a part of the phenomenon of submerged flow. Otherwise, the magnitude of the rise in water level must be estimated in fitting results of model tests to a stage-discharge relation downstream from the dam site. No satisfactory method of making this adjustment is available. It is probable that model tests indicate its magnitude more accurately than it can be computed.

Comparison of Model and Prototype.—On the whole, the agreement between model and prototype is considered satisfactory. Not much weight can be given to the three measurements made by surface velocity. If the coefficient 0.85 had been used for these measurements instead of 0.90, two of them would agree very well with the model. A coefficient of 0.85 is well within the range of possibility, but the originally estimated value of 0.90 has been retained. As may be seen from Fig. 55, the agreement between model and prototype except for the three surface velocity measurements is about as good as that between the discharge measurements themselves.

For estimating flood discharges from water level observations at dams, it would appear that the use of small-scale sectional models must be regarded as being as satisfactory as the current meter—from the standpoint of efficiency, far more so. In no case would an estimate of the backwater due to the dam, based on the model tests, have been in error by more than a few inches.

For all but two of the twenty-three measurements, the model indicated a discharge smaller than that measured on the prototype. To what extent this difference is chargeable to disproportionately large viscosity, surface tension, friction, and end effects is not known. Overregistration of the current meters may have accounted for some of the difference.

As previously suggested, the nonconformity of the curve for the lowest discharge in Fig. 53 to the general pattern for higher discharges is of special interest. It seems possible that the model fails for a discharge as low as this, but it cannot be disproved or substantiated from data now available.

CONCLUSIONS

The conclusions presented are necessarily tentative. However, they are considered to constitute a logical interpretation of the results of model tests and measurements of the University Dam.

(*a*) The effect of submergence on the discharge is affected by the shape of the spillway and perhaps by other factors. Data at present available are insufficient for generalization of the effect of submergence in terms of spillway shape. The use of "typical" data cannot be recommended.

(*b*) In general, it is not possible to express the effect of submergence upon the discharge by a single-valued relation between the submergence and the discharge ratio. In the range covered by these tests, the effect of submergence is greater for high discharges.

(*c*) If the tailwater elevation is measured at a sufficient distance from the dam, it is not necessary to consider the behavior of the nappe in determining the effect of submergence upon the discharge. For this and other reasons, the tailwater elevation should be measured beyond the immediate effects of the dam.

(*d*) Reasonably good agreement may be expected between spillway models and prototypes of the sizes used in these tests under submerged as well as free flow conditions.

Certain other observations might be presented as secondary or incidental conclusions, but these appear to have been covered to the extent that their importance justifies in the body of the paper.

ACKNOWLEDGMENT

Acknowledgment must be made of the assistance of many engineers. The possibilities of this study were recognized by E. W. Lane, M. Am. Soc. C. E., when an ice jam below the dam[11a] created unprecedented tailwater conditions. The prototype measurements were conducted by the writer under his direction. Some discharge measurements were made by the staff of the U. S. Geological Survey, under the direction of R. G. Kasel, M. Am. Soc. C. E., in connection with its regular stream-gaging work. The experiments on the model were conducted by C. L. Morgan, Jun. Am. Soc. C. E., under the joint direction of F. T. Mavis, M. Am. Soc. C. E., and the writer. The manuscript has been reviewed by F. W. Edwards, M. Am. Soc. C. E., and C. J. Posey, Assoc. M. Am. Soc. C. E., both of whom made valuable suggestions. Others who assisted in the project are: E. R. Van Driest, J. S. McNown, C. K. Willey, H. D. Brice, Juniors, Am. Soc. C. E., and G. L. Whitaker and B. D. Lind.

[11a] University Dam.

GRAND TOWER, MISSISSIPPI RIVER

By Frederick R. Brown,[12] Jun. Am. Soc. C. E.

Synopsis

The U. S. Waterways Experiment Station recently received from the U. S. Engineer Office, St. Louis (Mo.) District, field data that served to confirm the results obtained from a hydraulic model study (53) (54) conducted at the Experiment Station during 1936 and 1937 on a reach of the Mississippi River.[12a] A careful analysis of these data has been made and a comparison of the action of the prototype with the indications of the model furnishes the basis for this paper.

The Problem

The model study involved the development of an effective plan for improving the navigation channel of the Mississippi River between Mile 75 and Mile 80 above Cairo, Ill. At Mile 84.0 the Mississippi River enters a rock gorge, the bluffs of which confine the flow of the river to Mile 79.5. At the latter point the rock bluffs on the left bank of the Mississippi River recede, allowing the river to widen and to divide its flow between Grand Tower Island chute and the river channel along the right bluff line. The natural tendency of the river is to follow the chute channel. However, because of the more satisfactory navigation conditions that would prevail if the river could be made to develop the crossing to the right bluff line at Mile 79, two pile dikes were constructed in 1939 from the left bank at Mile 79.5 and Mile 79.2. These dikes effected considerable improvement in the navigation channel, but did not eliminate the need for periodic maintenance dredging through this crossing. The material dredged from the crossing was spoiled in front of, and off the end of, Dike 79.2 L and in the chute behind this dike in an attempt to confine the river flow to the crossing. Samples obtained after the completion of the model study indicated that the river-bed material in the vicinity was composed of sand, gravel, and coarse rock fragments.

The Model

The scale ratios, model to prototype, were as follows: Horizontal dimensions, 1 : 600; and vertical dimensions, 1 : 150. The model was of the movable bed type, with banks and overbank topography molded in concrete and the movable channel section molded in crushed coal. In addition to the slope scale of 4 : 1 induced by the difference in scale ratios, the model was given a slight additional slope sufficient to provide adequate movement of the bed material used. The scales used were within the range in which it has been found that velocity distributions and current directions can be reproduced accurately in models of wide, shallow rivers such as the Mississippi.

[12a] Adjacent to Grand Tower, Ill.

After a thorough adjustment and verification of the model, in which operating conditions were developed such that the movement of bed material in the model was consistent with that in the prototype, tests of plans were begun The testing procedure consisted of installing the elements of a proposed improvement plan in the model, the bed of which had been molded to conform to the 1936 prototype conditions, and operating the model in accordance with the stages of a modified form of the 1935 hydrograph (Fig. 56). The 1935 hydrograph included within its range an adequate distribution of critical high stages as well as normal and low stages. Therefore, since it was believed to embrace all conditions of flow likely to occur in the Grand Tower reach in the future, this hydrograph was selected for use in the model study. Both the dredging proposed in the improvement plan and the necessary maintenance dredging were simulated in the model.

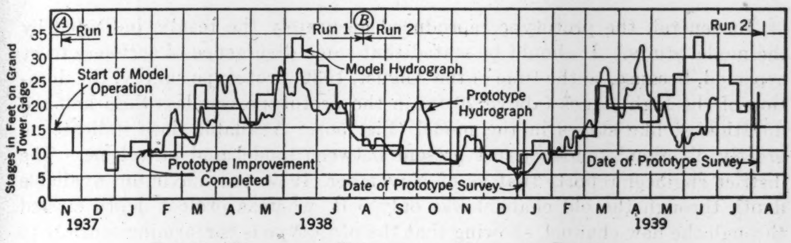

FIG. 56.—COMPARATIVE HYDROGRAPHS, MODEL AND PROTOTYPE

It was thought advisable to begin testing the improvement plan at a stage comparable to that expected in the prototype at the time of completion of the prototype improvement. It was believed that this completion would occur in November, 1937. Consequently, operation of the model was started with the 15-ft stage in November (modified 1935 hydrograph). Although dredging of the initial pilot channel in the prototype was not actually completed until January 30, 1938, the effect of the difference in time was not considered to be important.

MODEL AND PROTOTYPE IMPROVEMENT PLANS

The plan included the shortening of Dike 79.2 L and the addition of a 1,500-ft trail dike downstream from this dike, a dredge cut 250 ft wide to a depth of − 13 ft (low-water reference plane) along the right bank of Grand Tower Island, use of the dredge spoil chiefly to build up the left bank of the dredge cut, and riprap and mattress protection for the left bank of the dredge cut and for the trail dike.

In the prototype, the outer 600 ft of Dike 79.2 L was removed, the 1,500-ft trail dike was constructed, and revetments were placed along the left bank of the new channel during the period from August, 1937, to January, 1938. The pilot cut for the re-alined channel was made during several dredging periods—namely, September 28, 1937, to January 30, 1938; March 17 to May 28, 1938; and August 20 to October 31, 1938. This cut was more than 400 ft wide in the prototype in contrast to the 250-ft wide pilot cut in the model. It is understood that the dredge spoil (about 3,400,000 cu yd) was disposed generally in accordance with plans followed in the model test. In addition to the works scheduled in the improvement plan, prior to the August, 1939, prototype survey, the dike near Mile 79.1 on the right bank below Tower Rock was extended about 500 ft across the old channel. This extension was intended to aid the filling of the old channel.

COMPARISON OF PROTOTYPE AND MODEL RESULTS

In general, the prototype reproduced accurately the results indicated by the model study. It should be stated that some divergence of action is to be expected, because, to the time of the August, 1939, prototype survey, the duration of the high stages (above 20 ft) in the prototype was less than half the duration of like stages in the model (Fig. 56). Available data indicate no greatly divergent tendencies at present between model and prototype. The district engineer reports that as of November, 1939, the maximum available depth through the old channel was only 5 ft, whereas project depth existed through the new channel, showing that the prototype is conforming sensibly to the indications of the model. Careful examination of prototype and model data reveals the following interesting comparisons:

(*a*) Until the time of maintenance dredging in January, 1939, the re-alined channel in the prototype exhibited a persistent tendency to shoal. This agrees with the model results, since by the end of Run 1 the model channel had shoaled to a controlling depth of 5 ft below the low-water reference plane.

(*b*) Since the prototype maintenance dredging of January, 1939, the scour in the re-alined channel indicated in the model has occurred also in the prototype, although at a somewhat slower rate. This difference in rate of scour may be explained by the fact that the plan developed in the model was based on the assumption that the river bed in this vicinity was composed of average river sand containing only a small amount of larger material, whereas actual spoil samples (obtained when the actual improvement was undertaken) were found to contain 40% rock fragments and large gravel.

(*c*) A tendency to scour was noted in the model at the upper end of the old channel along the right bank, and tests indicated that this channel would continue to fill after each high stage. Thus far, alternate scouring and filling has also occurred in the prototype, with scouring predominating. It is to be noted that development of the re-alined prototype channel is not yet complete. It is believed probable, however, that, once this new channel has fully developed, the old channel will become filled substantially as predicted in the model.

The comparison of model and prototype behavior in the Grand Tower reach of the Mississippi River will be supplemented from time to time as additional prototype data are made available.

HYDRAULIC CONDITIONS TO LOCK AND DAM NO. 4

By William J. Hopkins,[13] Assoc. M. Am. Soc. C. E.

Synopsis

The new lock and dam here considered is located on the Monongahela River.[13a] Because of local conditions, the structure, as originally designed, was subjected to adverse currents that had an effect on the maneuverability of river vessels in the upper approach to the locks. At moderately high stages, the main currents, after sweeping around two comparatively sharp bends upstream, followed the lock side of the river, increased in velocity as they reached the upper approach, and then swung sharply across the lock entrance toward the center of the stream before discharging over the spillway section. Examination of the site and of the current conditions disclosed that the flow characteristics might have been due to several factors, or to a combination of any of these—namely, (*a*) the effect of the upstream bends on velocity and current distribution; (*b*) the effect of the hydrography in the vicinity of the approach on velocities and currents; and (*c*) the effect of a contraction in the stream cross section due to the lock and to the existence of a large bar along the shore opposite the lock chamber.

Fig. 57.—Modified Design of Upper Lock Approach

The existence of the foregoing condition prompted an investigation to be made by means of hydraulic model tests to study the causes of the current phenomena at the upper approach and to determine the most suitable means of improving the entrance conditions. On the basis of these studies, necessary

[13a] Lock and Dam No. 4, at Charleroi, Pa., about 40 river miles above the mouth of the stream, which is at Pittsburgh, Pa.

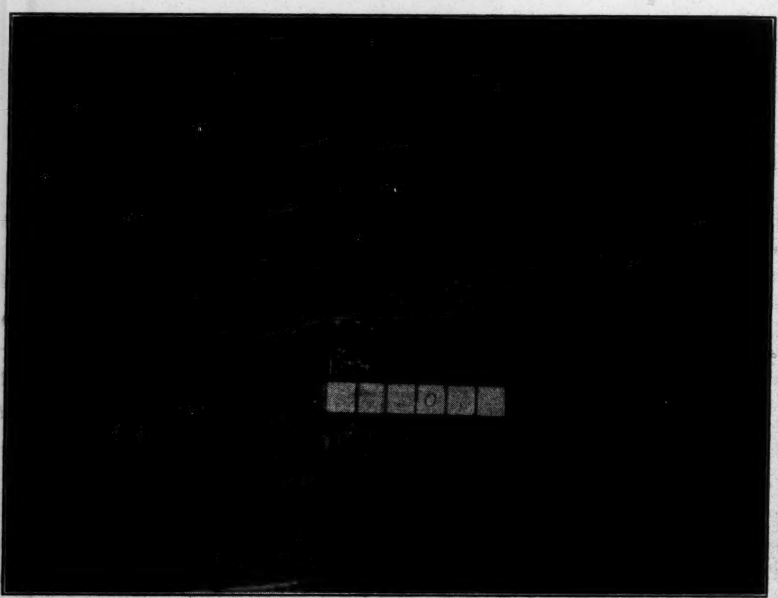

FIG. 58.—CONFETTI MOVEMENTS SHOWING CURRENT DIRECTIONS AND VELOCITIES; ORIGINAL DESIGN

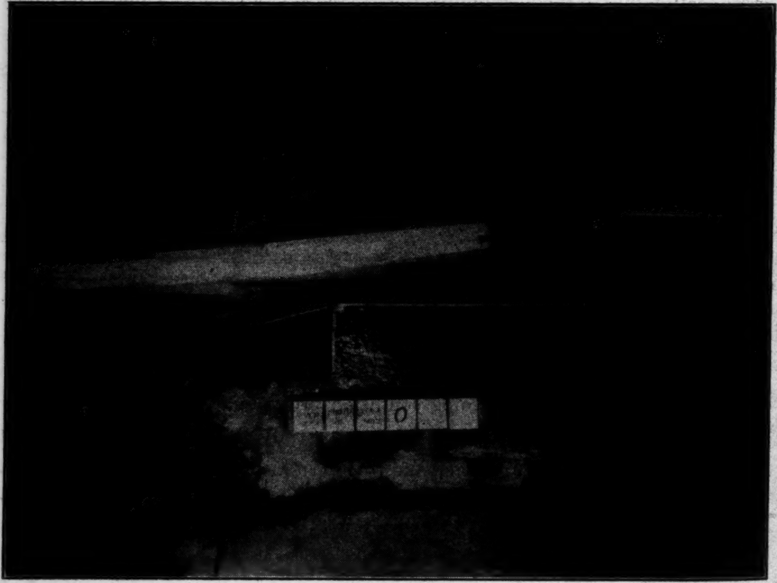

FIG. 59.—SHIFT OF MODEL TOW DUE TO CURRENTS IN THE ORIGINAL DESIGN

revisions were made in the upper approach to the lock and in the stream channel above the dam. These involved an extension to the guard wall, the construction of a spur dike upstream from the lock, and the removal of a portion of the bar opposite the lock chamber.

To determine the accuracy and the fidelity with which the model simulated the prototype conditions, certain field tests were conducted. The results of these investigations showed that, generally, hydraulic similarity between the model and prototype existed. As far as can be ascertained from the experience of navigators in traversing the upper approach to the lock chamber, the flow conditions have been considerably improved since the modifications in the upper pool were effected.

DESCRIPTION OF THE STRUCTURE

The dam is about 550 ft long from the left abutment to the lock, and is of the concrete gravity type. A modified, uncontrolled, ogee spillway section, with crest at El. 737.5 (mean sea level), is provided.

To accommodate the heavy river traffic in this vicinity, two locks having a lift of 10.6 ft are provided along the right bank of the stream. The land lock is 56 ft by 720 ft, and the river lock 56 ft by 360 ft. The tops of the guide and guard walls are at El. 749.0. As altered to produce suitable entrance conditions to the locks from above, the middle lock-wall and the guide and guard walls extend approximately 100 ft, 760 ft, and 855 ft, respectively, upstream from the upper gates of the land lock. In addition, a spur dike is provided at a point 1,600 ft upstream from the end of the guide wall. The dike is normal to the flow of the river and extends riverward from the shore to a point in line with the river face of the guide wall. It consists of a shell of steel sheet piling, backfilled for strength and stability. The general details of the structure, and the location of the component parts, are shown in Fig. 57.

THE MODEL TESTS

Approximately 2.4 miles of the river were reproduced in the model, the major part of the reach being upstream from the structure to develop accurately the flow characteristics at the upper approach. The model was undistorted, on a scale of 1 : 200, and was of the fixed-bed type built according to standard laboratory practice. All necessary details that might affect flow phenomena were reproduced faithfully to scale, including the lock and spillway and the topography in the immediate vicinity. The assumed channel roughness was reproduced as accurately as was physically practicable.

All basic tests for the design of the required improvements were made with the upper pool 0.5 ft below the top of the lock-walls. The flow corresponding to this condition was assumed to represent the greatest discharge under which the navigation facilities could be used. The tests consisted of analyses of the resulting velocities and currents, and of their effects on tows entering the locks from above. The investigations involved a determination of the flow condi-

SURFACE CURRENTS – UPPER APPROACH – MODEL

Prototype for the Altered Conditions of the River and Upper Lock Approach

tions for the original design, and of the separate and combined effects due to extension of the guide and guard walls, dredging in the upper lock approach, dredging of the bar opposite the lock chamber, and deflection of the flow by means of dikes of various proportions and located in various positions.

The data obtained from the model were of three types:

(*a*) Notes on visual inspection of the flow conditions;

(*b*) Photographic records of confetti movements and the paths traversed by model tows; and

(*c*) Actual measurements of the surface velocities in the critical areas.

In the analysis of the test data for the several proposed designs, the photographs disclosed the alinement, direction, and velocity of the currents by the alinement, direction, and length of the streaks. In addition, the photographic record revealed the effect of these currents on the travel of model tows that were allowed to glide toward the lock without artificial maneuvering. For a true comparison of the data in the various designs, the latter procedure was standardized by the use of a tow-projecting device that imparted to each tow the same initial velocity and direction. Samples of the photographic data for the original design are shown in Figs. 58 and 59. The surface velocity measurements were made in the region where they were believed to have the greatest bearing on the maneuverability of tows. This was accomplished by spanning the critical region with a piece of plate glass and marking thereon the location of floating paper disks at regular intervals of time.

To provide data for a comparison with the prototype results, and thereby furnish a means of verifying the model, special tests were run on the model for both the original and altered conditions of the prototype structure. These data were in the form of photographs of the current movements and an analysis of the surface velocities in the upper approach, the procedure during these tests being the same as the foregoing.

THE FIELD TESTS

The details of the structure, both in the model and the prototype, were the same, so that an exact comparison could be made for verification, except for the effects of surface tension and channel roughness—factors which were impossible of exact simulation in the model. Field tests were made both before and after the alterations had been made to the prototype.

The field data were necessarily confined to measurements of current directions and surface velocities. No data on tow movements, as affected by the flow in the approach, were obtained, since the artificial guiding of the tows in the prototype could in no way be simulated by tow movements in the model. The current directions and velocities were obtained by tracing the paths of floats in the river and recording their locations at regular intervals of time. This was accomplished by spotting the floats simultaneously with three surveyor's transits located at strategic points. Corrections were applied to the measurements for wind velocity by noting the wind effect on floats in the lock chamber.

VERIFICATION OF RESULTS AND CONCLUSIONS

A comparison of the data obtained on the model and in the field, in the form of current alinement and velocity vectors, is presented in Figs. 60 and 61. For the original design of the approach (Fig. 60), the operating conditions in the model and prototype were identical, corresponding to a head of 5.6 ft on the crest of the dam and to a discharge of 30,000 cu ft per sec (headwater elevation, 743.1). Operation for the revised design of the upper approach was not identical in the model and prototype. The head on the crest of the dam for this condition was 6.6 ft in the prototype as against 6.0 ft in the model, corresponding to flows of 40,000 and and 35,000 cu ft per sec, respectively (headwater elevations were 744.1 and 743.5 ft, respectively). The model tests had been conducted before an opportunity had presented itself for obtaining field measurements approximating the conditions tested in the model for the altered design, so that identical operation was not possible. However, the differences in head and discharge are not believed to be of sufficient magnitude to invalidate the results of the verification.

The degree of similarity between the model and prototype results is apparent from an examination of the data presented. Exact simulation by the model of the prototype phenomena was not attained; nor was it expected. Generally, the model data reveal close approximations for the magnitude of the prototype velocities, for the alinement of the currents, and for the nature and location of the quiescent pool formed downstream from the spur dike. A comparison of the data also shows a considerable reduction in the velocities of flow across the lock entrance and at the head of the guard wall, this condition existing in both the model and prototype.

In the course of the model and field tests, it was noted that slight surges in the flow occurred, especially in regions where an attempt was made to alter the flow characteristics, or where an obstruction to flow existed. Because of these surges, the resulting path of flow through any definite point for successive intervals of time was not identical, although the general pattern of flow for any area was approximately the same. A slight variation in the data should be expected, therefore, both in the model and prototype, and a comparison of the data should be made on the basis of general values and flow patterns rather than on the specific analysis of a particular flow line. Generally, therefore, the velocities, currents, and eddies in the model and prototype were similar.

CONCLUSION

It can be concluded that satisfactory verification of the model tests for the entrance conditions to the upper approach of the new lock and dam resulted. Subsequent experience in the maneuvering of tows in the reach of the stream in question has indicated it to be devoid of any serious hazards and to be satisfactory in every respect, which further attests to the success of the plan of alteration proposed as a result of the model tests. As in many other instances, model analysis in this case provided a direct approach to a problem that could not be solved by purely analytical methods.

II. NOTATION

The following symbols, used in the Symposium, conform essentially with "Letter Symbols for Hydraulics," prepared by a Committee of the American Standards Association with Society representation and approved by the Association in 1942.[14]

A = area of cross section, a subscript denoting the section location:

A_c = area of culverts;

A_l = area of lock chamber;

---

[14] ASA—Z10.2—1942.

b = length of weir crest;
C = discharge coefficient:
  C_l = lock coefficient;
  C_m = coefficient determined by model tests;
  C_q = coefficient of discharge;
D = diameter;
f = friction coefficient, subscripts m and p referring to model and prototype, respectively;
g = acceleration due to gravity;
H = head above a given datum plane: H_t = measured tailwater elevation, referred to the elevation of the crest;
h = pressure heads at selected sections indicated by appropriate subscripts:
  h_e = drop in pressure at entrance;
  h_f = loss of head due to friction;
  h_p = pressure head differential between two sections;
  h_v = head, velocity;
  h_x = pressure at any piezometer in the bellmouth;
K = a discharge coefficient defined by Eq. 11; also a constant in Eq. 3;
  K_o = observed constant in the rating equation (Table 2) for a flow meter;
  K_s = Scobey's friction coefficient;
  K_t = theoretical constant in the rating equation (Table 2) for a flow meter;
L = lengths, such as center-line distances from the bellmouth, with subscripts to denote section locations; the distance required to produce normal distribution below an intake in a smooth pipe:
  L_r = geometric scale ratio, $\frac{L_p}{L_m}$;
  L_x = a length factor;
n = constant exponent defined by Eq. 11;
p = pressure, in pounds per square foot; $\frac{p}{w}$ = pressure head, feet of water;
Q = time rate of discharge, subscripts m and p denoting model and prototype, respectively;
q = discharge per unit width;
$\mathbf{R}$ = Reynolds' number;
r = radius;
V = average velocity at a given cross section;
V_l = lock-chamber rate of rise or fall;
$\mathbf{W}$ = Weber number;
w = specific weight of water in pounds per cubic foot; $\frac{p}{w}$ = pressure head, feet of water;
y = depth of flow;
Δ = central angle.

DISCUSSION

A. E. **Niederhoff**,[15] Assoc. M. Am. Soc. C. E.—About the only thing that can be added to the thorough and fine paper by Messrs. Nelson and Hartigan is to call attention to corroborative evidence found on the West Coast. This evidence concerns two high lift locks with lifts of 66 ft and 45 ft, respectively.

The authors have revealed the fact that, where geometric similarity does not exist between model and prototype, correlation of test results is difficult. Of this there can be no doubt but, since total similarity, geometric and dynamic, can never be obtained when the same liquid is used in both model and prototype, one should not be too disturbed at failure to obtain exact quantitative results. After all, a model of any kind is not the answer to all questions on a subject. At the risk of seeming irreverent, the writer calls attention to the model husband who has been defined as "a small imitation of the real thing." Hydraulic models fall in the same category, and engineers do well to observe trends and characteristics in a model that are duplicated in the prototype. Actual measurements of time, velocity, forces, or discharges are done best on a full-size lock for possible design use on a similar structure.

Fig. 62(*a*) shows the filling of a model lock, utilizing a floor culvert and port system patterned after one of the locks discussed herein (66-ft lift). The same water disturbance in the model chamber will be observed in the prototype (see Fig. 62(*b*)) especially at the far end, near the lower miter gates. Also, when emptying the model chamber, the fountain effect below the lower miter gates is duplicated every time the 66-ft lock is emptied. It is interesting to note that, in spite of lack of exact similarity, the coefficient of filling for the model and prototype agreed within 1%. An average coefficient of filling was 0.83, and, for emptying, this coefficient dropped to 0.72.

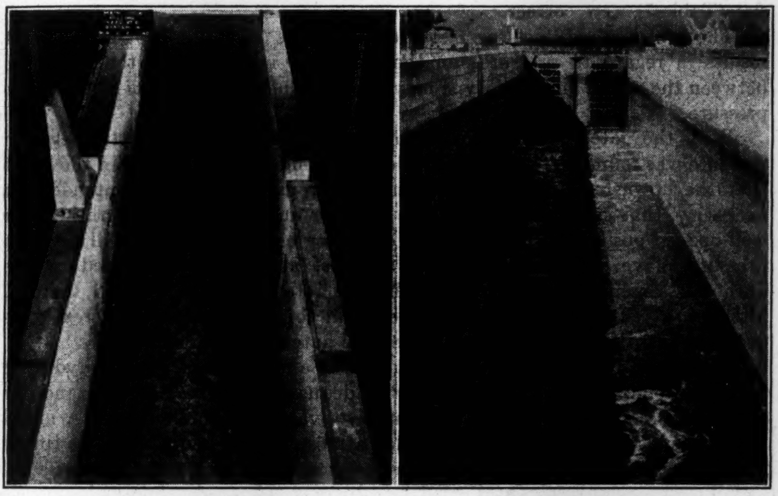
Hawser stresses in model lock chambers have been measured as a criterion for proper functioning for several years. However, to the writer's knowledge, only one attempt to measure hawser stresses has been made on a high lift lock. In 1940 a government derrick boat was moored by four lines to floating mooring bits in the 66-ft lock. Dynamometers were placed in these lines and readings were taken simultaneously at each 5 ft of lift. When plotted as a curve, the results showed that the maximum pull occurred when the valves were fully open and when discharge into the lock was a maximum. The curves showed the same family characteristics as those obtained in a model even if the actual magnitude of the pull on the lines was considerably greater than that shown in the model.

The distribution of water from ports in a lock chamber has been ably described by Messrs. Nelson and Hartigan, and it is only in deference to Southern California that the writer wishes to point to the full-scale results of the "manifold problem" investigated at the second high lock mentioned herein

---

[15] Senior Structural Engr., U. S. Engr. Dept.

(45-ft lift). Southern California was a factor in this test because the grapefruit used as floaters came from Coachella Valley. These juicy, yellow spheres were placed just upstream from the filling valves, and timed and counted as they emerged from the several chamber ports. In this particular case, most of the grapefruit, and therefore most of the water, came from the port farthest upstream in the chamber.



(a) Model (Head, 47.6 Ft) (b) Prototype (Head, 49.0 Ft)

FIG. 62.—DISTURBED WATER CONDITION WHEN LOCK CHAMBER IS BEING FILLED

Model tests have shown the necessity for relieving entrapped air in a culvert system if the lock is to be filled efficiently. The conditions at the 45-ft lock at the time of conversion from a tandem lock to a single lift of 45 ft were such that only one large vent hole per culvert could reasonably be drilled. This hole was 20 in. in diameter. When completed, it worked beautifully, sending a geyser of air and water 60 ft into the air above the top of the lock-wall and adding another spectacle to the scenic beauty of the region.

When the diameter of the vent hole was reduced to 10 in. by placing a pierced diaphragm over the end of the vent pipe, the water no longer shot out of the vent pipe but entrapped air exploded into the lock chamber. Cutting the effective vent hole to a diameter of only 4 in. merely made the chamber explosions more violent and more prolonged.

C. I. GRIMM,[16] M. AM. SOC. C. E.—A number of acceptable formulas have been developed for use in determining the crest profile of an overflow concrete spillway. The profile of the crest of the spillway reported by Messrs. Stevens and Cochrane comes within the limits of these formulas and, therefore, may be considered as a conventional shape. Computations for a thin jet were made as a guide to design. These showed that, with the gate in the downstream position, the jet followed quite close to the crest profile, but that with the gate in the upstream position it departed considerably. It was not considered practicable, however, to design the profile so that there would be no departure in this case. These calculations would raise doubt as to whether the positive pressures indicated by the model with the gate in the upstream slot (Table 7) were correct.

---

[16] Formerly with U. S. Engr. Dept., Portland, Ore. (Mr. Grimm died on December 1, 1942.)

The prototype studies seem to prove that the model did not give correct results in regard to pressures on the crest and indicate that the difference between the model and prototype may be due to non-similitude of atmospheric pressure.

With the gate in the downstream slot on the prototype, little negative pressure was found. The upstream slot is for emergency use only in the event that the downstream slot is out of use for repairs. It is not intended, or necessary, that gates in these slots be used for fine regulation, but rather in a well-opened position. As a practical operating condition, only small negative pressures have existed on the spillway crest at the dam discussed by the authors. Examination has shown the concrete to be undamaged thereby, although extensive damage to the piers and some damage to the crest have occurred just downstream from the vertical gate slots.

Comparison of prototypes with models is an important step in hydraulic investigations that has been entirely inadequate in scope, to date, and the study by Messrs. Stevens and Cochrane is a valuable contribution. A model study of spillway crests under controlled atmospheric pressure would be timely and of decided value as a research project to supplement present knowledge.

JOE W. JOHNSON,[17] ASSOC. M. AM. SOC. C. E.—The various papers included in this Symposium indicate that a wide variety of hydraulic problems is susceptible to investigation by means of models. All of the papers are important contributions to a field in which the literature is rather meager.

Of particular interest to the writer were the papers by Mr. Hickox and by Mr. Soucek on spillway coefficients. In the investigations described in these two papers, a period of five years was required to obtain the various data. Mr. Hickox describes prototype observations and compares them with model studies that were made when the structure was in the design stage. On the other hand, Mr. Soucek describes model studies and compares the data with past observations on an existing structure. The sequence of the observations is unimportant for giving valuable information on conformity between model and prototype. Model studies made prior to the construction of a prototype give valuable assistance in obtaining the best design, but model studies made of existing structures are more likely to be academic in character. Somewhat between these two limits was a model study conducted at the University of California at Berkeley, Calif., on the spillway crest of the Upper Narrows Dam on the Yuba River. This investigation (58) was intended primarily to provide (1) a check on the assumed discharge curve of the spillway, and (2)

measurements of the profile of the nappe at various discharges for the purpose of predicting the point where the water would strike the stream bed at the base of the dam.

The Upper Narrows Dam, intended for flood control and as a debris barrier, is of the constant-angle arch type with a curved crest (Fig. 63). The length of the spillway crest is divided into twelve sections by piers 5 ft thick. Except for the two end sections, all sections have a length of 100 ft from center line to center line of piers. To take the normal flows over the dam a center section, 4 ft lower than the other sections, is provided. The length of this section is 189.4 ft, excluding piers, and the remaining crest length, 908.4 ft. The elevation of the depressed section is 527 ft, and the elevation of low flow in the original stream channel was 291.2 ft.

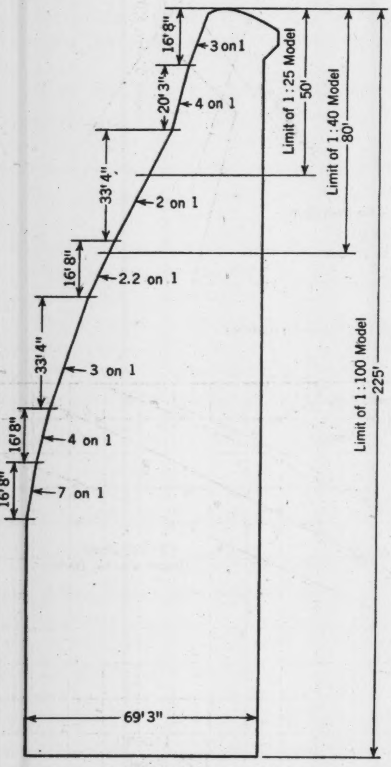

FIG. 65.—CROSS SECTION OF 1 : 100 MODEL (Distances Given in Prototype Values)

From a consideration of the model and prototype measurements on the Keokuk Dam on the Mississippi River (21*a*), the designers assumed the relationship between the weir coefficient C (computed from Eq. 13) and the energy head shown in Fig. 64. The following discharge formula was then determined from a logarithmic plot of head versus discharge per foot of crest, the discharge being determined from Eq. 13 and the weir coefficient curve of Fig. 64:

$$Q = 2.62\, H^{1.66} \ldots\ldots (15)$$

Fig. 63 shows a comparison of the crest profiles of the Keokuk Dam and Upper Narrows Dam.

To check Eq. 15 and provide data on the profile of the nappe, three models were constructed using scales of 1 : 25, 1 : 40, and 1 : 100 (see Fig. 65). The two larger scales were used primarily for the determination of the discharge characteristics of the spillway at the dam, and the 1 : 100 model was used to determine the profile of the nappe.

The models were tested in a flume 6 in. wide and 3 ft high, equipped with a forebay and baffles. Discharge was measured by means of an orifice meter in the supply line leading from a constant-head tank. All models were of smooth, varnished wood, 6 in. wide, and approximately 2 ft high. They thus represented only the upper part of the dam (depending on the scale), as shown in Fig. 65. The heads used in the analysis included the measured depth above the crest and the velocity head in the approach channel and, therefore, represented the energy head. Observations were taken with heads varying from 0.030 ft to 0.450 ft. Because of the relatively strong surface tension forces at the heads below 0.03 ft, the nappe would cling to the face of the model—a condition which probably would not exist on the prototype at a corresponding head. A high degree of turbulence in the approach channel prevented accurate readings of the head for heads greater than 0.450. All runs were made with the nappe completely aerated by means of a 1-in. pipe through which air could flow to the underside of the nappe.

To determine whether frictional forces had any significant effect on the weir characteristics over the range of flow under investigation, tests were conducted on the 1 : 25 and 1 : 40 models with a smooth, varnished surface and with a sand-rough surface. The roughened surface was obtained by sprinkling sand, which passed the 100-mesh sieve and was retained on the 200-mesh sieve, on the freshly varnished surface of the model.

Fig. 64 shows the relation between the weir coefficient and the energy head for the various models. The values for the 1 : 25 and 1 : 40 models, whether with a smooth or sand surface, agree very well and can be represented by an average curve. In addition, the results from the 1 : 100 model, which are consistently lower than the larger models, are shown in Fig. 64.

By using the average curve drawn through the experimental points for the 1 : 25 and 1 : 40 models (Fig. 64), values of discharge were computed for various assumed values of head. A plot of discharge versus head on logarithmic paper gave the relationship:

$$Q = 2.79\,H^{1.62} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

For comparative purposes, the data of Mr. Soucek are also of interest. Thus, the mean curve through the experimental points in his head-coefficient relation obtained by model studies (Fig. 51) is also plotted in Fig. 64. This curve follows quite closely the designer's curve based on the Keokuk experiments, and such agreement is to be expected when it is considered how similar the profiles of Keokuk Dam and the dam discussed by Mr. Soucek are to each other (Fig. 63). A more definite measure of the agreement between the various studies is obtained if the head-discharge relation shown in Fig. 55 is plotted on logarithmic paper. If the discharge per foot is considered instead of the total discharge, this plot yields the equation

$$Q = 2.85\,H^{1.62} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Comparing Eq. 17 with Eqs. 15 and 16, it is found that below a head of about 3 ft the various equations give practically the same discharge. For a head of 10 ft, Eqs. 15 and 17 give discharges that are about 3% greater than the Upper Narrows Dam (Eq. 16). For almost all design problems this agreement can be considered as well within the limits of error to which certain basic design data, such as the "maximum" spillway discharge, can be estimated.

V. L. Streeter,[18] **Assoc. M. Am. Soc. C. E.**—Those in charge of hydraulic laboratories are inclined to look to model studies for the answer to all hydraulic questions, when the application of fundamental hydraulic design principles will frequently give more reliable information at a small fraction of the cost. In many cases, a more detailed and searching analysis of the problem before the model is constructed would show that a complete model study of all hydraulic features is unnecessary. To be specific, in the case of pressure and discharge tests on the 102-in. river outlets described by Messrs. Warnock and Dewey, a more reliable discharge may be obtained by computation than by scaling up the model discharge. Although Froude's number must be used to scale the discharge, the value of friction factor, which depends on the Reynolds number, cannot be determined from the model.

The writer, while working in the hydraulic laboratory of the U. S. Bureau of Reclamation, prepared a prototype discharge curve for the intermediate outlets before the model was constructed. For values of the head, H, greater than 40 ft, one outlet has the discharge

$$Q = 340\,H^{0.5} \qquad (18)$$

in which, supplementing the Symposium nomenclature, H is the total head above the center of the exit, in feet. Eq. 18 is based on:

(1) A loss at the entrance and gate section of one tenth the velocity head in the pipe;

(2) A friction factor $f = 0.0073$ for the 225 ft of pipe; and

(3) A loss of six hundredths of the velocity head for elbow and converging section. The friction factor was determined by a consideration of smooth pipe friction factors for the same Reynolds numbers, as given by the Nikuradse (59) formula. The curve resulting from this discharge equation is plotted in Fig. 66 with those given in Fig. 13. This computed discharge curve seems more reliable than the curve through the points obtained from the prototype discharge measurements. Curve 4, representing the prototype discharge measurements, has a loss of head proportional to $V^{2.13}$, in which V is the average velocity in the 102-in. outlet. It is significant that Messrs. Warnock and Dewey did not use the discharge measurements as a basis for computing the prototype friction factor.

The prototype friction factors as shown in Fig. 6 may easily be 25% too high. To determine accurately the value of f for a pipe with small length-diameter ratio, velocity distributions should be obtained at each end of the test section. At the downstream end of the bellmouth the velocity distribution would be practically uniform, but about fifty diameters farther downstream the velocity would assume its characteristic distribution for the particular Reynolds number. The value of the kinetic energy correction factor for a friction factor 0.0073 would be about 1.02 (60). For a head of 150 ft, the velocity head is about 83.6 ft. Neglecting the kinetic energy correction factor could change the head loss by two hundredths of the velocity head, or 1.67 ft. The head loss due to friction in 40 ft of outlet should be about 2.87 ft. Hence a change in kinetic energy correction factor of 0.011 in the reach would change the friction factor by 25%.

---

[18] Associate Prof., Hydraulics, Illinois Inst. of Technology, Chicago, Ill.

In many cases the best method of predicting prototype performance is first to formulate analytical relationships for model performance. When relationships are established so that model performance may be predicted and verified by tests, the analytical relationships may be altered to fit the prototype. The discharge curve for the outlet works is an example of this method. Using the best values of f, and minor losses, the discharge for the model may be obtained in equation form, and the various losses may then be adjusted to agree with model experimental data. When this is accomplished, the value of f should be changed to that anticipated in the prototype. As the minor losses are more dependent on Froude's number, they should not require alteration. This method permits an evaluation of model performance in terms of the prototype when the Reynolds number effects are important.

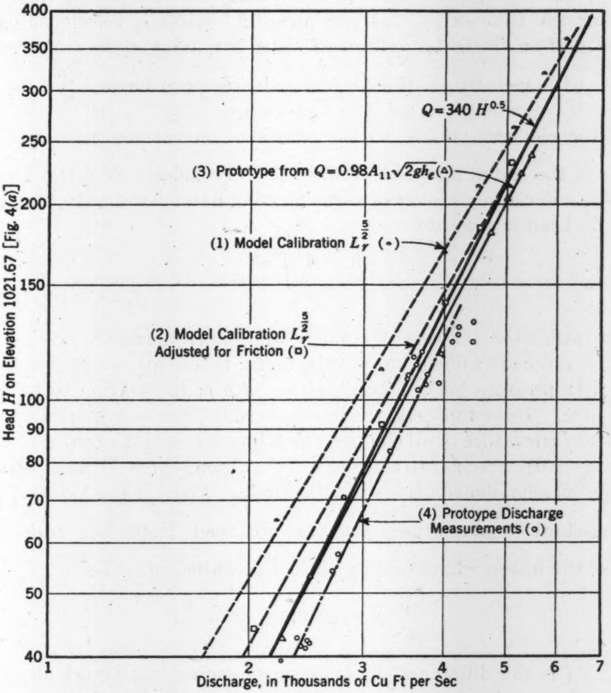

Fig. 66.—Comparison of Discharges (See Fig. 13)

The authors' explanation of the discrepancy in pressures between the model and prototype—that is, due to unstable flow—is not clear (heading:

"Examples of Quantitative Comparisons: Pressure Drop in Elbow and Cone"). For a scale of 1 : 17 the Reynolds number for the model would be about one seventieth as much as for the prototype. For the outlet model the Reynolds number would be between 300,000 and 1,000,000—a range in which there is no reason to expect unstable flow.

The observed pressure distributions through the elbow and cone, as given in Fig. 5, do not appear susceptible to analysis. Forgetting the observed results, for the time being, the fundamental hydraulic relationships will be examined. If an elemental volume of water is moving along a curved path of radius, r, with velocity, v, the difference in pressure heads, $\frac{dp}{w}$, on the two sides of the element normal to the radius of curvature, must be $\frac{v^2}{g\,r}\,dr$, in which dr is the radial distance between the two sides, and g the acceleration of gravity. For a finite layer of water moving in a curved path, the difference in pressure head is given by

$$\frac{\Delta p}{w} = \frac{1}{g}\int \frac{v^2}{r}\,dr \ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

which is integrated between the outer and inner filaments of flow. If the values of v and r are known for each filament, this relation will give the proper difference in pressure head, assuming the path of integration to be in a horizontal plane. Unfortunately these relationships are not known. Assuming the center of curvature of all elements on a line through the center of curvature of the elbow perpendicular to the plane of the elbow, three different assumptions regarding velocity distributions will be made. First, if the velocity is everywhere constant in magnitude, the pressure head drop, $\frac{\Delta p}{w}$, from crown to invert for the intermediate outlets, in feet of water would be

$$\frac{\Delta p}{w} = 0.00000206\,Q^2 - \Delta z \ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

in which Δz is the difference in elevation of crown and invert along a radial line from the center of curvature. The term Δz corrects the formula for the case in which the filaments are not in a horizontal plane. If, instead of the foregoing velocity assumption, it is assumed that the magnitude of the velocity varies inversely as the distance from the center of curvature, as with the "free vortex," the pressure head drop in feet of water becomes

$$\frac{\Delta p}{w} = 0.00000216\,Q^2 - \Delta z \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

Finally, assuming that the velocity magnitude varies directly as the distance from center of curvature, as with the "forced vortex," the pressure head drop becomes

$$\frac{\Delta p}{w} = 0.00000205\,Q^2 - \Delta z \ldots\ldots\ldots\ldots\ldots\ldots (20c)$$

It is surprising how well Eqs. 20 agree. One is led to think the velocity distribution is not too important. Approximately the pressure drop is found to vary inversely with the radius of curvature for each assumption regarding velocity distribution. If the elbow turned through an angle of, say, 180°, there would be no question as to whether the center of curvature used was substantially correct. For an angle 41° 19′, however, the radius of curvature of the filaments may for the most part be greater than that of the elbow. Using the results of the model studies (Fig. 5) to determine this radius for the assumption of constant velocity, the radius of curvature at the center line is found to be 52.8 ft. This is based on an average of eight values taken from the two higher model heads shown in Fig. 5 for distances from the axis of 195, 200, 205, and 210 ft. The spread was from 48 ft to 60.5 ft. Using the value 52.8 ft, the formula becomes

$$\frac{\Delta p}{w} = 0.00000155\, Q^2 - \Delta z \ldots\ldots\ldots\ldots\ldots\ldots (20d)$$

Checking Eq. 20*d* against the prototype measurements in Fig. 5 corresponding to those for the model, the pressure head drops are found to agree on the average within 2.4%, with a spread from − 11% to + 4.5%.

This is a method, therefore, of predicting the difference in pressure between prototype crown and invert from model studies. From considerations of equilibrium in the elbow, the pressure rise at the crown may be shown to equal the pressure drop at the invert, assuming a "forced vortex" velocity distribution. Approximately the same results will be obtained for the other two assumptions. The pressure at the center line would not change because of the centrifugal forces set up in the elbow. The poor agreement shown in Fig. 5 would appear due to errors in model piezometer pressures.

This discussion has been submitted in order to emphasize the importance of careful analytical study of hydraulic design features before construction of a model and the continued analytical attitude during model testing and evaluation of results.

Glen N. Cox,[19] M. Am. Soc. C. E.—The various papers of this Symposium are a valuable addition to the literature on the operation and reliability of hydraulic models.

The paper by Mr. Soucek is of special interest to the writer since it deals with a dam operating as a submerged weir. The definition of submergence quoted by Mr. Soucek infers that a weir can only be submerged if the elevation of the tailwater is above the crest of the weir. This assumption is satisfactory for any weir not having a sharp crest. However, a sharp-crested weir behaves as a submerged weir when the tailwater elevation is materially lower than the crest elevation. This is true because it is impossible to ventilate the underside of the nappe properly from the sharp-crested weir when the tailwater elevation approaches the crest elevation. A desirable definition of a submerged weir is as follows:

---

[19] Prof., Mechanics and Hydraulics, Louisiana State Univ., Baton Rouge, La.

> A weir is said to be submerged whenever the tailwater rises to such an elevation that the discharge over the weir is affected.

Mr. Soucek is correct when he states that the discharge over an ogee crest is not materially affected when the submergence is less than 45%.

Mr. Soucek chose appropriate words in the statement (see heading, "Comment: Measurement of Tailwater Elevation")—

> "* * * the water level near the dam is at a lower elevation than farther downstream. The reason for a negative slope in this reach is a readjustment of velocity distribution which has an effect that is similar, as regards energy transfer, to the recovery of pressure head which occurs in the diffusing cone of a venturi meter."

The downstream pressure should be measured at the point of minimum pressure, namely, at the throat of the venturi tube. The head recovered downstream from the throat of the venturi meter varies between rather wide limits and depends upon the original turbulence, the angle of divergence, the viscosity of the fluid, the roughness of the surface, and possibly upon other factors. Although it would be possible to calibrate a given tube and thus obtain a relationship between the discharge and over-all pressure drop for a given fluid, it would not be reasonable to expect that the same relationship would hold for the same tube with a different piping arrangement or in transporting a fluid of decidedly different physical properties. Neither could the calibration be used for tubes of other proportions and angles of divergence. On the other hand, calibrations that are based upon a downstream pressure reading taken at the throat can be used for predicting the discharge from other tubes and for other fluids flowing in the calibrated tube.

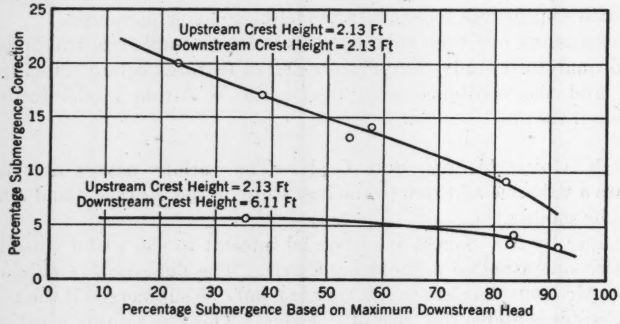

Fig. 67.—Correction Curve for Obtaining Percentage Submergence at Low Point Near Crest

The same reasoning applies to the submerged weir. The magnitude of the recovery head downstream from the low pressure point depends upon the proportions and roughness of the channel downstream from the dam. No two natural channels could be expected to be similar in this reach, nor would the reaches upstream and downstream from the crest be similar. Fig. 67 shows the difference in percentage submergence when the tailwater elevation is measured near the dam as compared to the value when the tailwater elevation is measured at the point of maximum recovery. These values were measured upon a suppressed weir, there being no lateral expansion downstream from the crest. The transfer of energy is more efficient when the proportionate amount of the expansion is reduced. For these reasons, a consideration of model laws would reveal that it would be poor practice to include any more variables than necessary in the test arrangement and that, therefore, the tailwater elevation should be measured near the dam.

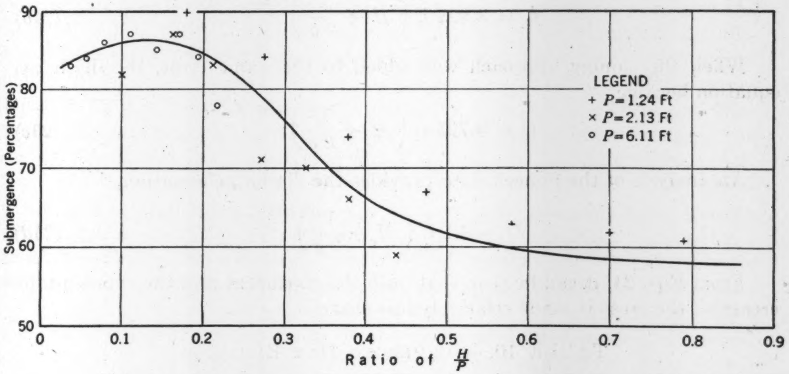

FIG. 68.—MAXIMUM SUBMERGENCE FOR PLUNGING NAPPE FLOW

Mr. Soucek referred to the maximum submergence for which the plunging nappe condition might be maintained. Fig. 68 shows a different method of presenting this subject. The values used in Fig. 68 were obtained from the Wisconsin study (45).

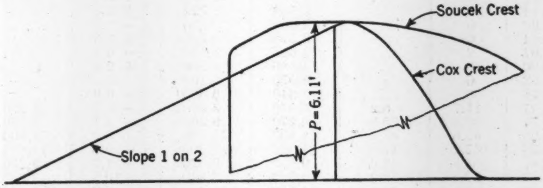

FIG. 69.—COMPARATIVE CREST SECTIONS

The discharge over an ogee, submerged weir can be represented by the formula

$$Q = C\,L\left(H + \frac{V^2}{2\,g}\right)^n \qquad (21a)$$

in which Q is the time rate of discharge, in cubic feet per second; L is the length of the crest, in feet; H is the measured head on the dam referred to the crest, in feet; V is the average upstream velocity of flow; g is the acceleration due to gravity; C is a coefficient; and n is an exponent. Both C and n depend upon the section of the crest, the type of flow, the submergence, and possibly other factors. The section of the ogee crest used for the Wisconsin tests is shown in Fig. 69, in which the section of the Soucek crest has been added for comparative purposes. The discharge equation for the Cox crest with the vertical back was

$$Q = 3.895\, L \left(H + \frac{V^2}{2\, g} \right)^{1.625} \qquad \text{(21b)}$$

When the sloping approach was added to this same crest, the discharge equation became

$$Q = 3.725\, L \left(H + \frac{V^2}{2\, g} \right)^{1.596} \qquad \text{(21c)}$$

An analysis of the Soucek data provides the discharge equation,

$$Q = 3.1\, L \left(H + \frac{V^2}{2\, g} \right)^{1.55} \qquad \text{(21d)}$$

From Eqs. 21, it can be seen that both the coefficient and the exponent decrease as the crest is made relatively less sharp.

7,340	4.13	89.2	86.0	6,740	7,520	+ 2.5	6,130	−9.1

The submerged discharge equation (plunging nappe) for the Cox crest having the sloping approach was given by Eq. 21a, in which

$$C = 3.725 - \frac{0.193\, S^2}{1.15 - S} \qquad \text{(22a)}$$

$$n = 1.596 - \frac{0.035\, S^2}{2 - S} \qquad \text{(22b)}$$

and S is the submergence ratio based upon a tailwater reading taken near the crest. When $S = 0$, the values of C and n given by Eqs. 22 become the same as those given in Eq. 21*c*. A trial solution also shows only slight variation in C and n for values of S less than 0.5, which supports Mr. Soucek's conclusion that the submergence need not be considered for values of S less than 0.45.

The data contained in Table 9 have been computed to furnish Table 10. The discharges in Col. 6 have been obtained by use of Eq. 21*d*. Judging by the values in Col. 6, the Soucek crest experienced little, or no, diminution of discharge because of submergence. Also, the measured discharges for the higher submergences are in excess of the true discharges and to find a satisfying explanation for this conclusion becomes necessary. During the testing at Wisconsin (45), the writer observed that there was an upstream current near the floor of the channel on the upstream side of the weir for all flow conditions and that there was an upstream current near the floor of the channel on the downstream side for the flowing nappe type of flow. Mr. Soucek states that the gaging station was 470 ft downstream from the dam and that no gaging was taken when the ice jam was closer than 500 ft of the dam (see heading, "Observations on Prototype"). From this statement, it must be concluded that one or more gagings were made within 30 ft of the ice jam. The proximity of this barrier and the depth of the water on the upstream side of it certainly would indicate that an upstream current existed near the bed of the river at the gaging station. Such an upstream current could not have been detected by means of the Price current meter, which was used in making the gaging, and a computed discharge in excess of the true discharge would result from such an upstream current.

Should the same reducing factors for C and n be assumed to apply for the Soucek crest as did apply for the Cox crest with the approach, the following equations would result:

$$C = 3.1 - \frac{0.193\,S^2}{1.15 - S} \qquad \text{(23a)}$$

and

$$n = 1.55 - \frac{0.035\,S^2}{2 - S} \qquad \text{(23b)}$$

Eqs. 21*a* and 23 have been used to compute the discharge over the Soucek crest and the results appear in Table 10, Col. 8. These values have been compared with the discharges which were indicated by the model (Col. 5) to give Col. 9, Table 10. Considering the rather great difference in the section of the crests, the agreement between the values in Cols. 5 and 8 is remarkable, and it must be concluded that the model tests were conducted very carefully by Mr. Soucek.

GRAHAM WALTON,[20] ASSOC. M. AM. SOC. C. E.—The information on submerged weir discharge in Mr. Soucek's paper is of particular interest. Weirs are frequently installed in previously constructed channels to measure sewage or industrial wastes. Restrictions in available head loss may require submerged flow conditions, at least during periods of peak flow.

---

[20] Instr., Civ. Eng., Univ. of Wisconsin, Madison, Wis.

In 1936 a weir of trapezoidal cross section (Fig. 70), with a surface of smooth cement-sand mortar, was calibrated at the hydraulic laboratory of the University of Wisconsin, at Madison, for the express purpose of measuring waste discharge at a paper mill. Special attention was given to the investigation of the effect of submergence on the discharge. The heads were measured, 3 and 5 ft, respectively, upstream and downstream from the upstream edge of the weir crest.

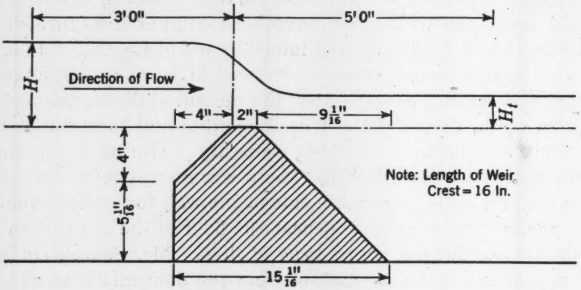

FIG. 70.—WEIR CROSS SECTION

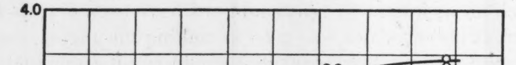

FIG. 71.—COEFFICIENT *C* FOR WEIR WITH FREE DISCHARGE

Test results are summarized in Fig. 71, which gives the coefficient of discharge *C*, as determined for

$$Q = C\,L\left(H + 1.2\,\frac{V^2}{2\,g}\right)^{\frac{3}{2}} \quad \text{(24)}$$

Fig. 72 shows the ratio of submerged to free discharge for various submergences. The latter is plotted as a single-valued function and is surprising in its agreement with U. S. Deep Waterways tests (*42a*). There is some indication, however, that, had it been possible to increase the distance at which the head

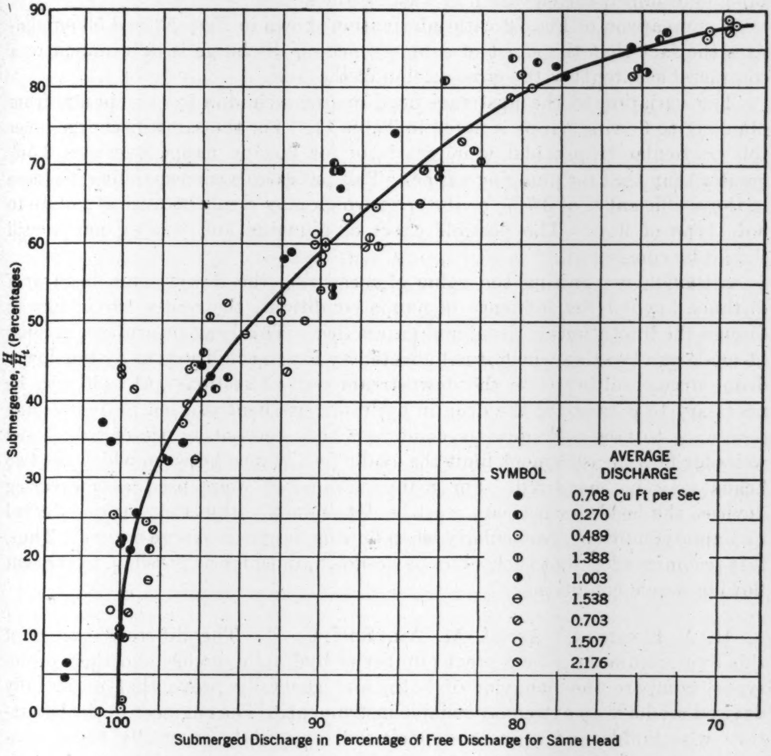

FIG. 72

TABLE 11.—VARIATION OF HEAD ON A WEIR WITH THE TRANSITION FROM A PLUNGING TO A FLOWING NAPPE

Description	DISCHARGE, IN CUBIC FEET PER SECOND:								
	0.268	0.490	0.704	0.707	0.999	1.389	1.509	1.536	2.16

Transition (±)	36	39?	42?	....	47	51	53	....	60

downstream was measured, a family of curves might have been obtained. Careful examination of the original data shows abnormal change in downstream head with transition from plunging to flowing nappe. This should not be the case with constant discharge if the control section downstream from the weir alone determined the elevation of water surface.

A comparison of Fig. 72 with information shown in Figs. 52 and 53 emphasizes the fact that the effect of submergence on discharge is determined to a considerable extent by the cross section of the weir.

The variation of the upstream head on the weir due to the change from plunging to flowing nappe is noted in Table 11. For the same discharge, over this particular trapezoidal weir, the head for flowing nappe averages 2.5% greater than that for plunging nappe. This indicates a corresponding decrease in the coefficient *C* of 3.7%, or the error which may result because of failure to note type of flow. The possible effect of plunging and flowing nappe still should be considered.

Although recognizing the value of measuring the downstream head at a distance beyond the influence of nappe conditions, the writer would like to discuss the limitations encountered in practice. This head measurement must be made at a location which is not affected by nappe conditions or by the downdrop curve resulting from the downstream control section. Also, it may be necessary to correct for the drop in hydraulic gradient utilized in overcoming resistance to flow. Frequently conditions that necessitate use of submerged weirs for flow measurement limit the available distance between which the two heads may be measured. For many submerged weirs used as measuring devices, the head downstream must be determined within that region affected by nappe conditions, particularly when flowing nappe discharge occurs. Thus, it is recommended that such weirs be designed, in so far as possible, to prevent flowing nappe conditions.

H. A. Einstein,[21] Assoc. M. Am. Soc. C. E.—The different papers of this Symposium describe a great number of hydraulic models and their prototypes, compare the behavior of both, and generally prove that a carefully devised model is an extremely reliable instrument. The engineer in the laboratory who builds and operates models will appreciate especially these comparisons because, more than anybody else, he knows the possible reasons why similitude may be disturbed.

In several of the papers, friction has been given as the cause for deviation between model and prototype. It is known that friction along rough walls will conform, in different scales, according to Froude's law if the roughness is reduced in the model according to the scale of all other lengths and if this reduced roughness combined with the reduced Reynold's number of the flow still represents a rough wall. If this is not the case, disagreement is inevitable. This case occurs most frequently in connection with hydraulic structures, which are generally rather smooth in the prototype to reduce friction. Usually, this friction is unimportant or may be corrected by calculation. There are cases, however, in which the true reproduction of this friction is essential.

---

[21] Hydr. Engr., SCS, U. S. Dept. of Agriculture, Greenville, S. C.

In these cases a method of distortion may be used which proves very effective for river models, many of which must be distorted to keep the flow turbulent. While visiting the hydraulic laboratory in Vicksburg, Miss., where such models usually can be found, the writer was astonished to see how much the natural roughness of the model must be increased to counteract the effect of the distortion on the friction. It is clear, therefore, that a comparatively slight distortion of any hydraulic model will allow an effective increase of the wall roughness which may just make the difference between rough and smooth.

This raises the question of the reliability of distorted hydraulic models in general. It was somewhat disappointing that no quantitative comparison of any such model with its prototype could be offered in this Symposium. Elsewhere (17), the writer, with R. Müller, has described the conditions under which a distorted model with movable bed will conform with the prototype, giving the results of the application of the method to a river model.

The model in this case was that of the Rhine River above the Lake of Constance (62). Within the first 20-mile stretch above the lake the stream loses the greater part of its bed load by sedimentation in its own bed. This gradual decrease of the rate of bed-load transport down this stretch is parallel with a gradual decrease of the slope. The alarming speed with which the bed was filling up forced the responsible authorities to study all possible ways of relieving the dangerous situation. The model in question was intended to represent a section of the river in the upper part of the 20 miles and to reveal constructive measures which would increase the river's capacity for bed load without increased slope. The rules for transportation in the model had to be found empirically because no theory of any kind existed at the time. Therefore, a series of trials was made to duplicate, in the model, the changes of the river bed that had taken place during past years using Froude's law for the flow. When agreement was satisfactory, the main experiments were started. However, only the preliminary experiments can be used in comparing the model with the prototype, because the corresponding measurements in the prototype applied to them only.

The measurements in the river, in addition to data not used in this connection, include (*a*) several sets of cross sections, (*b*) the hydrographs for the time intervals between these surveys, and (*c*) velocity and slope measurements at different stages. Mechanical analyses of the bed material were available for the entire 20-mile stretch. A set of bed-load measurements using a calibrated trap gave the rates of bed-load movement at one section for different stages and checked very well with calculations using the bed-load formula, commonly referred to as the Swiss formula. This same formula was used to calculate the transportation at other sections of the stretch, and the difference of transport during certain periods of time was checked against the deposition between the sections and in the lake. The measurements within this rather intricate system agreed astonishingly well, thus introducing the rates of transportation into the list of variables measured in the prototype.

The model was built entirely empirically. Originally it was supposed to be geometrically undistorted except for the grain size in the movable bed which was composed of coal. The low specific gravity of the grains should counteract the effect of the large grain sizes as far as transportation is concerned. However, it was known at the time from similar models that the time ratio chosen for transportation must be entirely different from the time ratio of the flow proper. By trial and error a ratio of 360 gave, very closely, the same configuration of the model bed as was found in the prototype and was used thereafter throughout the entire study.

All the evidence seemed to indicate that the model was similar to the prototype, but the quantitative rules of this similarity were not discovered until more than a year later, when Froude's law was abandoned as a basis of comparison and was replaced by a new system of equations describing similarity in a distorted model.

Instead of a general ratio for all different variables of the dimension of length, four different ratios were used:

(1) λ for lengths in direction of the main flow;
(2) ϕ for the width, a horizontal length perpendicular to the main flow;
(3) χ for the height, any vertical length; and
(4) δ for the grain diameters.

An additional distortion was allowed by the separate introduction of

(5) ξ for the ratio of slopes, independent from λ and χ.

Each common Greek letter represents the ratio of a certain measure in nature over the corresponding measure in the model. Also, for time, a distortion is allowed by the separate introduction of:

(6) τ for any time concerning the movement of water; and
(7) θ for any time concerning the movement of sediment.

A number of constants enter any hydraulic problem involving bed-load movement. The acceleration of gravity and the density of the water are assumed to be equal in model and prototype:

(8) η may be the ratio of the effective specific gravities of the sediments under water. Their specific pore volumes in the bed are assumed to be equal;

(9) ζ is the ratio of the constants in the Manning-Strickler formula as explained subsequently; and

(10) σ is the ratio of the constants F introduced in the bed-load formula (63).

For convenience, three more ratios of composite variables are introduced and defined by the three equations:

(11) γ as the ratio of the specific bed-load transport defined by

$$\gamma \theta = \eta \lambda \chi \ldots\ldots (25a)$$

(12) μ as the ratio of corresponding masses of water defined by

$$\mu = \lambda \phi \chi \ldots\ldots (25b)$$

and

(13) ψ as the ratio of corresponding discharges, defined by

$$\psi = \mu \, \tau^{-1} \qquad (25c)$$

Four more equations can be introduced describing similarity between model and prototype. For the distorted model the general Froude's law reduces to

$$\chi = \lambda^2 \, \tau^{-2} \qquad (25d)$$

expressing the fact that any heights are correlated like values of $\frac{v^2}{2g}$. The next equation expresses the similarity of corresponding bed friction. Friction in a stream with bed-load movement is usually of the rough type, especially if the bed material is as coarse as that in the Rhine River. Therefore, friction may be described by Manning's formula. The same formula must be used in both model and prototype; otherwise the principal characteristic of similitude is lost, because corresponding values of the same type must be correlated by a constant factor. The constant n in Manning's formula can be expressed for a granular bed, according to A. Strickler (64) as the sixth root of a representative grain diameter of the bed divided by another constant. This new constant will vary only slightly for extremely low Reynolds numbers and with the intensity Φ of bed-load transportation. In ratios the Manning-Strickler formula, therefore, reads

$$\lambda \, \tau^{-1} = \zeta \, \delta^{-1/6} \, \xi^{1/2} \, \chi^{2/3} \qquad (25e)$$

The two remaining equations are derived from the postulated identity of the transportation formula. Using the $(\Psi$–$\Phi)$-relationship, the values of both Ψ and Φ must be the same for corresponding points in model and prototype as long as the same $(\Psi$–$\Phi)$-curve holds in both scales. If the Reynolds number of the flow in the model is extremely low (as was the case for the Rhine River model), a slightly different $(\Psi$–$\Phi)$-curve applies. This difference of curve is taken care of by the introduction of ratios (14–15) α and β for corresponding Φ and Ψ values, respectively:

$$\alpha = \gamma \, \sigma^{-1} \, \eta^{-3/2} \, \delta^{-3/2} \qquad (25f)$$

and

$$\beta = \eta \, \delta \, \xi^{-1} \, \chi^{-1} \qquad (25g)$$

Flume experiments with the model sediment under flow conditions similar to those in the model resulted in a $(\Psi$–$\Phi)$-curve that is lower and flatter than normal, suggesting that both α and β are smaller than unity.

Even when this method of comparison was used, the similitude did not seem satisfactory. Only when the model was interpreted as duplication of the flow at another section of the river farther downstream in the 20-mile stretch was satisfactory similitude achieved.

Table 12 shows a comparison of the values for the fifteen ratios as derived from direct measurements in model and prototype (Col. 6) with those computed according to Froude's law (Col. 3), with those using Eqs. 25 for a distorted model introducing α and β equal to 1 (Col. 4) and for a distorted model choosing α and β according to special flume studies (Col. 5). Only normal flows were studied in the model. The measured length ratio λ as well as the χ values, therefore, were obtained from the comparison of the characteristic average form of the sediment bars in model and prototype. The model appears to be almost undistorted geometrically except for being tilted downstream, as shown in Table 12.

Parameters ψ, η, and ϕ have been chosen; θ was determined by trial and error; and α, β, ζ, and σ are measured independent of the model. A comparison of the values in Cols. 5 and 6 shows remarkably close agreement of all the seven remaining calculated ratios with the measurement. Col. 4, Table 12, may illustrate how easily the entire system can be disrupted by the wrong assumption of any constants in the equations involved. These data may prove that a quantitatively similar river model with lightweight material in the bed is possible and that its behavior can be predicted. A certain distortion, especially of the time scale, is unavoidable. Because of these distortions Froude's law cannot be applied. Instead, a system of empirical formulas with their constants describing bed friction and bed movement determines the different ratios. The same equations must be applicable to both model and prototype if similarity is to prevail. All constants in these equations must be known for both scales if the different ratios are to be predicted.

TABLE 12.—COMPUTED AND MEASURED RATIOS FOR THE RHINE RIVER MODEL

Ratio	Symbol	Calculated			Measured
		Froude	Distorted		
(1)	(2)	(3)	(4)	(5)	(6)
Φ-values	α	1	1	0.595	0.5–0.7
Ψ-values	β	1	1	0.838	0.8–1.0
Width	ϕ	100	100	100	100
Time (sediment)	θ	10	360	360	360
Strickler-constant	ζ	1	0.80	0.80	0.80
Density (sediment)	η	1	7.7	7.7	7.7
Settling-constant	σ	1	1	1	1
Discharges	ψ	10^5	10^5	10^5	10^5
Length	$\lambda=\alpha\,\beta^{9/4}\,\phi^{-1/3}\,\theta\,\zeta^{-9/2}\,\eta^{-7/4}\,\sigma\,\psi^{1/3}$	100	276	110	100–130
Height	$\chi=\phi^{-2/3}\,\psi^{2/3}$	100	100	100	95–104
Slope	$\xi=\beta^{1/2}\,\zeta^{-3}\,\eta^{-1/2}$	1	0.704	0.645	0.6–0.65
Time (hydraulic)	$\tau=\alpha\,\beta^{9/4}\,\theta\,\zeta^{-9/2}\,\eta^{-7/4}\,\sigma$	10	27.6	11.0	9.3–13.7
Specific transportation	$\gamma=\alpha\,\beta^{9/4}\,\phi^{-1}\,\zeta^{-9/2}\,\eta^{-3/4}\,\sigma\,\psi$	10^3	591	236	250
Hydraulic masses	$\mu=\alpha\,\beta^{9/4}\,\theta\,\zeta^{-9/2}\,\eta^{-7/4}\,\sigma\,\psi$	10^6	2.76×10^6	1.1×10^6	$(0.95–1.35)\times10^6$
Grain diameter	$\delta=\beta^{3/2}\,\phi^{-2/3}\,\zeta^{-3}\,\eta^{-3/2}\,\psi^{2/3}$	100	9.14	7.0	6.8–7.2

Unfortunately, knowledge of the fundamental laws of bed movement in large streams is still unsatisfactory. Therefore, it is not possible to build quantitative models for large streams with fine sediment. In this case, only qualitative models producing qualitative results can be built; but even those qualitative results cannot be trusted unless it is possible to find in each model a number of qualitative checks such as those described by Mr. Brown in his excellent paper about "Development of Mississippi River Channel." The care with which statements in general are made in Mr. Brown's paper illustrates the unreliability of such models and the great danger of drawing erroneous conclusions from them. It is hoped that as a result of basic research investigators soon will find the fundamental laws needed for quantitative model studies in this field.

K. G. TOWER,[22] JUN. AM. SOC. C. E.—The "Foreword" to the admirable series of papers appearing in this Symposium could advantageously have been more lengthy and explicit. In explanation of the objective of the research the rather bald question is stated: "Does the prototype act as the model predicted?" This question will cause the uninitiated to query: How, then, if at this late date such a question must be asked, has the art and science of hydraulic model testing reached its present prominence? For all practical purposes, of course, with the exception of the relatively infrequent case where air entrainment or the pressure of the atmosphere (or a combination of both) may be critical factors, models operated at atmospheric pressures will give a thoroughly reliable solution to problems which, in many cases, if there is an alternative, are susceptible to but questionable mathematical analyses.

With perhaps a few exceptions, those engineers who have had recourse to the hydraulic laboratory for the solution of a specific problem have been "sold" on the idea of model testing. They have seen the solution obtained in the laboratory verified by the prototype. So far as has been observed and checked by rough field measurements, qualitatively and quantitatively, for all practical purposes the prototype has performed as predicted by the model. The irrigation-canal check-drop investigation presented by Messrs. Warnock and Dewey is typical of the type of problem that has been solved repeatedly in the past to the entire satisfaction of all concerned, and upon which successful solutions the present excellent reputation and reliance in hydraulic model testing have been founded.

Thus, qualitatively at least, with the exceptions noted, the question of the "Foreword" need not be asked of hydraulic laboratory personnel. The question should be reworded to read: "To what degree do quantitative measurements recorded in the laboratory differ from those obtained in the field?" Viewed in the light of the restated objective of this research, the Symposium is seen to represent the first organized public expression of the manner in which hydraulic designers and laboratory technicians are striving toward the achievement of perfection. Those who have participated in developing the technique and interpretation of hydraulic model studies from an awkward adolescence to a confident maturity within the past decade can consider themselves as having engaged in a job well done.

The attainment of perfection in any activity is highly desirable, and is always praiseworthy, even in those instances where the activity itself may be of doubtful merit. It is hoped, however, that before those engaged in the direction of hydraulic laboratories definitely conclude to spend all of their available spare time and funds in an effort to perfect the interpretation of results obtained from model studies that thought first be given to furnishing the hydraulic designer with reliable basic data which will permit final and economic solutions of his everyday problems. In metaphor, before worrying about the twine in the binder, first learn how to plow.

---

[22] Associate Engr., U. S. Engr. Dept., Portland, Ore.

An important task of the future is the elimination of the need for a number of the hydraulic tests of models accepted by many agencies at present as standard practice. Typical structures frequently constructed should be analyzed in the hydraulic laboratory in such a manner that the data obtained therein, when correlated with other modifying or confirming data from prototype measurements, would constitute a reliable guide to the hydraulic designer and eliminate the necessity for the continual repetition year after year of the construction and testing of models of structures which are nearly identical.

Spillway crests furnish possibly the best example of the case in point. It is a recognized fact that the highest discharge coefficients are obtained with crests properly designed and shaped to fit the lower nappe curve of a discharge sheet over a sharp-crested weir. Hydraulic laboratories should endeavor, at the earliest opportunity, to supplement information already available on the curve of the sharp-crested weir lower nappe and the entire matter should be placed on record in such a manner that no hydraulic designer in the future, by reason of the lack of adequate information, need be found recommending a spillway shaped, for example, similar to the one examined by Mr. Soucek and illustrated in Fig. 50 in his study of submerged flow, "Meter Measurements of Dam Discharge." Stilling basins and transitions at the entrances to conduits are additional structural features deserving critical and intensive examination for the purpose of design standardization and the elimination of routine hydraulic model testing. The use of the three structural features mentioned requires the greater part of the work involved in the hydraulic design of dams and control works, and more comprehensive information on them is needed daily at the drafting boards of organizations engaged in this work.

The suggested research program will have to be conducted principally in laboratories as there are insufficient suitable existing full-scale structures, even if all were investigated, to contribute an appreciable quantity of the necessary basic data. Those existing structures that are suitable, however, well may be examined for data to be used as a check of the models at one or more stages of the variations in them which will be required.

The fact that at this late date the meager store of basic hydraulic information makes the proposal contained herein necessary is sufficient evidence that considerable fortitude, initiative, and skill will be demanded of those participating in the program. The magnitude of the work required is such that the program will have to be deferred until after the war. In the meantime, the practicing hydraulic engineer will welcome any prototype study that contributes to his working knowledge regardless of whether or not the intent of such study is merely to confirm or deny data obtained from a particular hydraulic model.

R. J. Pafford, Jr.,[23] Esq.—Individually the papers are an interesting and enlightening addition to the literature on hydraulic model practice and hydraulic design, for which the various authors are to be commended. Collected together in this Symposium, they represent important contributions toward more effective and more comprehensive use of the hydraulic model as an instrument of design, through the illustration of the wide field of problems susceptible to model analyses, and toward better general understanding of how this tool can be improved further by the illustrations of both its capabilities and its present limitations.

---

[23] Engr. (Hydr.), U. S. Engr. Office, Omaha, Nebr.

Considering the subject matter of the Symposium as a whole, the paper by Messrs. Warnock and Dewey is particularly thought provoking. There is urgent need for much more prototype data, both for evaluation of accuracy of the model and for direct use in design. This calls for the creation of greater interest on the part of all concerned, and for still greater cooperation in overcoming the difficulties of making prototype measurements. Past lack of general interest undoubtedly has been contributed to by both the model worker and the designer of hydraulic structures. Too great enthusiasm of the model worker arising from his intense interest in his tool in many cases has tended to "oversell" the capabilities of the model; and also, in many cases, there has been a tendency of the designer to present his finished product as if it were the best and final answer to a given set of conditions rather than just a good design which will perform satisfactorily, but which undoubtedly could be improved either in performance characteristics, economy, or both, if better information were at his disposal. A more realistic attitude on the part of both can contribute materially to greater general interest and, in turn, to greater opportunity for the collection of needed prototype data, even where the expenses of observations may be high.

The numerous difficulties involved in obtaining accurate prototype data make this indeed an exasperating and expensive field, yet fascinating, in the writer's experience at least, because of these very difficulties. The utmost in ingenuity and the fullest possible interchange in ideas are essential. With reference to difficulties with equipment such as that used in measuring spillway bucket velocities and water-surface elevations over spillways as mentioned by Messrs. Warnock and Dewey, the following suggestions are offered for general consideration in future cases of this nature. Tubes leading to observation galleries, in many cases, can be kept open by regular flushing with clear water at frequent intervals from the time of installation until all desired performance data are collected. This often will be a nuisance to operating personnel, and of course in some instances will be impracticable; but then, why install the tubes if they are to become unserviceable before data can be collected? There also seems a possibility that small tubes placed without sharp bends, with a flexible corrosion-resisting wire to be removed only during tests extending their full length (same idea as is used in an automobile hand-throttle control except that the wire would be pulled entirely from the tube during tests) might solve this clogging problem at some locations. The problem of coating or plugging of pitot-tube openings is not necessarily beyond solution either. It would seem that some kind of protective cover which might be removed either directly or by remote control just prior to a test could be devised for many installations. Turning to the problem of measurements of water surface of the flow over spillway sections of a dam, it appears that for at least some cases not complicated by spray from gates at partial opening, some relatively inexpensive method employing a narrow intense light beam and transit observations of the "spot" projected on the water surface (possibly coupled in some cases with measurement of reflection angles) could be utilized. Developments along the lines of sonic or electronic soundings also would seem to hold considerable promise for the future, perhaps especially in cases complicated by spray and foam on top of the "solid" jet.

As mentioned in the Warnock-Dewey paper, still and motion pictures of all flow conditions observed both in laboratory and field are indeed invaluable for purposes of comparison of model and prototype performance. On this score, the writer desires to emphasize the desirability of complete pictorial records of model performance from viewpoints that can be duplicated in the field as well as from vantage points possible in the laboratory which may better illustrate performances of certain features of the model but which are impractical in the field. It has been the writer's unfortunate experience, which is feared not unique, to fail on several occasions in attempts to compile fully satisfactory comparative pictorial records because the only laboratory pictures were taken through the sides of glass-walled flumes or from points which would require that the prototype photographer be suspended in mid-air over the stream below a dam. On the other hand, really excellent photographic comparisons are possible, as illustrated by Fig. 1, when model photographs from proper angles are available. For most effective photographic comparison of model and prototype performance, attention to relative focal lengths of camera lenses used in the laboratory and in the field, to insure similar perspectives of the photographs, is almost as important as the position of the camera.

In 1942 the writer had a convincing demonstration of the qualitative accuracy of the hydraulic model in a field not covered by the papers comprising the Symposium. In connection with design of a spillway stilling basin utilizing baffle piers for energy dissipation, there was some concern for a possible cavitation hazard, and extensive model investigations were made under the writer's general supervision in two leading hydraulic laboratories. The test method in one involved the measurement and analysis of pressures that occurred on baffle surfaces in a model under atmospheric pressure; the other involved visual inspection and interpretation of the performance of a model erected in a vacuum tank apparatus which enabled the reproduction of pressures in the correct scale ratio. To enable the best possible interpretation of the tests for the structure being designed, both laboratories first conducted tests on models of an existing stilling basin also dependent on baffle piers for energy dissipation where some pitting in certain areas along the sides of the baffle piers had actually occurred during the passage of an extreme flood. So far as the main test program was concerned, it is sufficient to state that the results of independently conducted tests at each laboratory were in reasonable agreement with conditions observed at the existing prototype and with conditions indicated at the other laboratory, and that a design involving partly streamlined baffle piers was evolved. The original descriptions and photographs of conditions at the existing structure had indicated pitting only along certain areas on the sides of the baffle piers. During testing of the model of this structure in the vacuum tank, it was seen that conditions along the stilling basin floor in certain areas between the baffle piers were apparently nearly as severe as along the sides of the baffle piers where pitting had occurred and there were also indications of incipience of cavitation at the extreme upstream edge of the tops of the baffles. Incidentally, indications of areas on the sides of the baffles in which cavitation might be suspected in the model were in excellent general agreement with pitted areas in the prototype. Some time after observing the foregoing phenomena at the laboratory, the writer visited the existing prototype for the specific purpose of further investigation of the extent of pitting in the stilling basin area. Visual inspection revealed a minor degree of pitting at the leading edge of the tops of the baffle piers in the areas indicated by the model. The stilling basin floor was covered by a thin layer of mud and 4 or 5 ft of murky water, making visual inspection there impracticable at the time. Careful probing, however, definitely established that there was considerable pitting of the apron floor in the very areas indicated by the model. As nearly as could be determined by "feel" through the sticks used for probing, the degree and depth of pitting were very similar to the pitting on the sides of the baffle piers where the depth ranged up to 2 or 3 in. below the original concrete surface.

EDWARD H. SCHULZ,[24] M. AM. SOC. C. E.—The physical comparisons of models in this Symposium cover a wide range of structures, including irrigation works, discharge outlets, dry dock suction chambers, lock construction, dam outlets, discharge and pressure heads, spillway coefficients, meter measurements, river improvement, and lock approaches.

There are discussions of qualitative and quantitative comparisons, the latter of which were found to be the more valuable and important. The ratio of prototype to model has a wide range from 1 : 5 to 1 : 600. Hydraulic models should be on as large a scale as reasonable. Perhaps there has been too little interest in comparing performance of the prototype with the model, partly due to the difficulty of making measurements. The accuracy of measurements is important in the prototype as well as in the model. Some of the more difficult determinations are slope, velocity, discharge, pressure, friction, etc., and these are more difficult in closed circuits than in open ones, and more important for the prototype than for model studies. Studies as to erosion, bar movement, etc., may be necessary.

Geometric similarity is very important. The comparisons should cover the range of hydraulic conditions. The cost of prototype field measurements may be a deterrent.

Conclusions in the Symposium, based on the tests of various structures, show that performances generally have been in line with the model tests. Such tests are an excellent help to the engineer. Model conditions, in general, were substantiated by the prototypes, especially where geometric similarity existed. Discrepancies were within 5%, and probably less than would have occurred without such model tests. There were some anomalous results, however, such as pressure head comparisons. The meter measurements of dam discharge of the model were about 5% less than those of the prototype. The general agreement was satisfactory. On the river improvement the prototype reproduced the results indicated by the model. Some diversion was to be expected. On the lock approaches there was satisfactory verification.

---

[24] Col., Corps of Engrs., U. S. Army (*Retired*), Berkeley, Calif.

In conclusion, the writer considers model tests very useful in the study and correction of hydraulic relations and conditions. In building any structure where such studies and comparisons are likely to be needed and where the expense is justified, provision should be made to incorporate appropriate accessories and equipment in the prototype during construction. Measurements can then be made more readily and tests can be conducted at any time within the limits of the structure and the range of the hydraulic conditions to be expected.

F. T. Mavis,[25] M. Am. Soc. C. E.—In a singularly complete manner Mr. Soucek has presented the results of his laboratory studies and their comparisons with observations of a prototype. The systematic relationship between relative discharge (submerged to free) and submergence shown in Figs. 52 and 53 reflects the precision of the laboratory measurements. It is clear from Fig. 53, as Mr. Soucek states in his first conclusion, that generalizations of the effect of spillway profile and absolute discharge should be accepted with caution as a basis for estimating precisely the relationship between headwater head, submergence ratio, and discharge over a spillway.

Profile of Model *B*, in Inches

x	*y* Below Crest	
0"	11.25" and 1.45"	
2	0.25	
4	0.00	Crest
6	0.30	
8	0.75	
10	1.85	
12	3.00

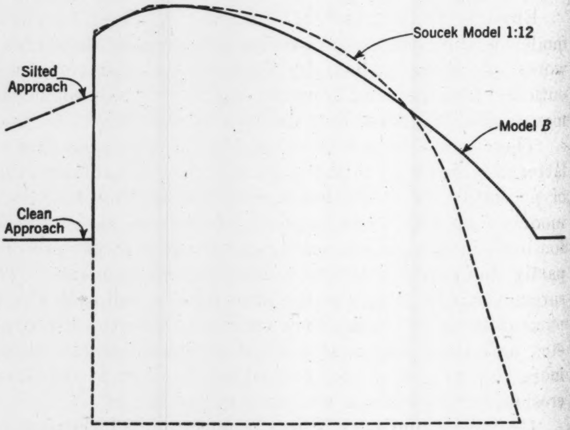

Fig. 73.—Comparison of Models

The verification by laboratory test that the relation between submergence and discharge was unaffected by the condition of the nappe, whether plunging or flowing, should dispel misgivings for one shape of spillway at least. An interesting problem of hydromechanics may lie behind the data plotted in Fig. 54.

---

[25] Head and Prof., Civ. Eng. Dept., and Acting Head, Dept. of Eng. Mechanics, The Pennsylvania State College, State College, Pa.

In 1934 the writer conducted a brief series of tests at the University of Iowa, Iowa City, Iowa, on a model 11.25 in. high, designated Model B, in Fig. 73. The model profile discussed by Mr. Soucek is shown for comparison.

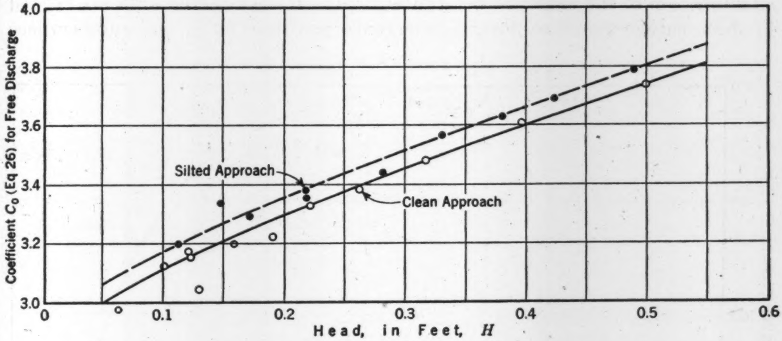

FIG. 74.—TESTS OF MODEL B; FREE FLOW

Model B was tested in a glass-walled flume 12 in. wide under two conditions—"clean approach" with a level approach channel; and "silted approach" with a sand fill 1 on 2.5 intersecting the upstream face of the model 4 in. below the crest.

Fig. 74 shows the relation between coefficient for free discharge

$$C_0 = \frac{Q_0}{L\,H^{1.5}} \qquad (26)$$

and head for both "clean approach" and "silted approach." Analysis of data on this basis is simpler than analysis based on Eq. 13. If a model is truly representative of its prototype, either analysis leads precisely to the same conclusion. Used discretely either analysis leads to a valid engineering conclusion.

Fig. 75 shows the relationship between submergence percentage, p, and the ratio of submerged to free discharge as expressed by the formula

$$\frac{C}{C_0} = 0.01\,[100 - 2^{0.2(p-70)}] \qquad (27)$$

Opposite each plotted point is a figure representing the corresponding discharge, q, in cubic feet per second per linear foot of crest. The absolute rate of discharge, q, may be recognized in Fig. 75 as an independent variable. Although the data plotted in Fig. 75 might be presented in support of Mr. Soucek's discussion of Fig. 53, one may ask whether the ultimate uses of the data warrant the refinement of analysis in this instance. To explore this point the generalized analysis of data from tests of Model B were compared with data reported by Mr. Soucek in Cols. 2 and 3 of Table 9.

Fig. 76 shows the coefficient of discharge for the prototype:

$$C = \frac{Q}{L\,H^{1.5}} \qquad (28)$$

as a function of the observed headwater depth, H. Observed data are classed in three categories—free flow, submergence less than 60%, and submergence greater than 60%. Fig. 76 shows also the curves based on tests of Model B for clean approach and silted approach. The conversion from model to prototype was based on Froude's law. Note that the scatter of points in the first category (free flow) is of the order of 5% of the coefficient of discharge. According to Fig. 53, the submergence would have to exceed 80% before the actual discharge would be reduced correspondingly below that calculated for free discharge. Hence, as a tentative premise one may assume that only the last three field observations in the third category (Table 9) are significantly below a valid general curve relating coefficient of discharge and head on prototype as shown in Fig. 76. Tentatively, then, the relationship between head and free discharge for Model B and the prototype seems verified by Fig. 76.

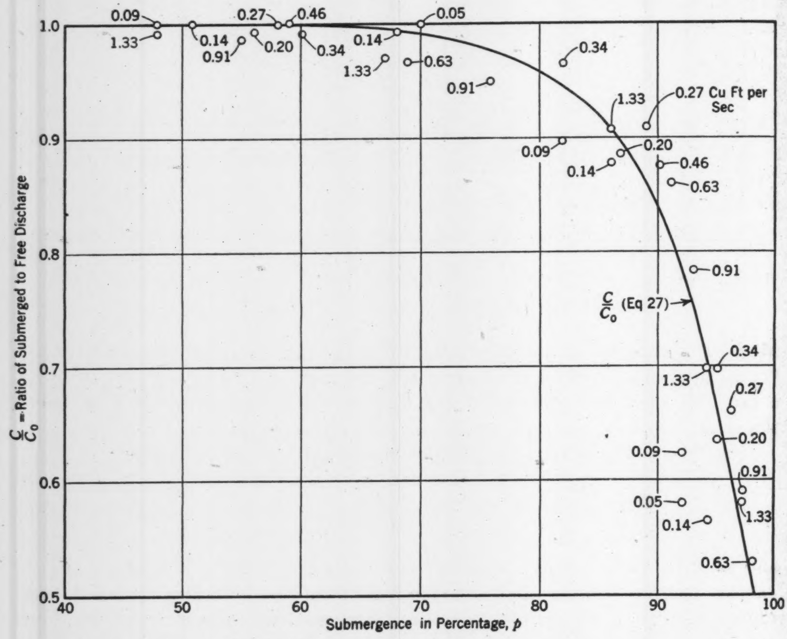

FIG. 75.—EFFECTS OF SUBMERGENCE; MODEL B

As stated, Eq. 27 in Fig. 75 shows an average curve relating the ratio of submerged to free discharge $\frac{C}{C_0}$, and percentage submergence, p. Although this equation appears complex, it means that the ratio of submerged to free discharge, $\frac{C}{C_0}$, is reduced from unity by 1.0% if the submergence is 70%;

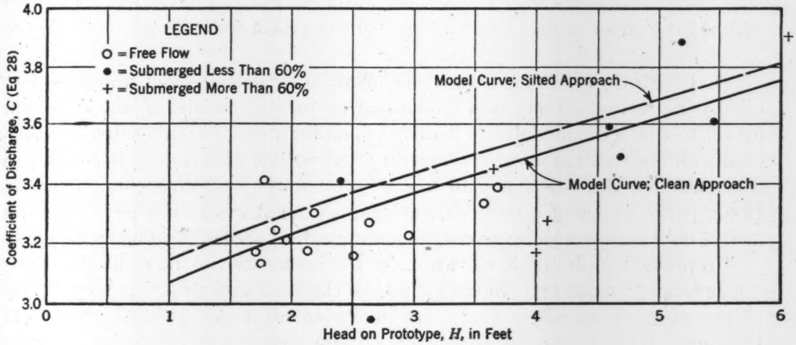

FIG. 76.—OBSERVATIONS OF PROTOTYPE

this percentage reduction is successively doubled for each additional 5% of submergence. For example,

For a submergence ratio (%) of:	the reduction of $\frac{C}{C_0}$ is	and the ratio $\frac{C}{C_0}$ is
70	0.01	0.99
75	0.02	0.98
80	0.04	0.96
85	0.08	0.92
90	0.16	0.84
95	0.32	0.68

As a final step, the writer compared observed data on the prototype reported in Table 9 with corresponding data computed on the basis of tests of Model B for both free and silted approaches. Adjusted discharge (Col. 2, Table 9), headwater depth (Col. 3), and tailwater depth (Col. 6), were used as the basis for a spillway 273.50 ft long. The maximum difference between field observations and corresponding calculations based on tests of Model B with the generalized submergence correction (Fig. 75) was 11% for the model with clean approach and 13% for the model with silted approach. These values correspond to a maximum difference of 15% in Table 9. The mean absolute percentage difference between Model B and the prototype was 3.8% for the clean approach and 4.2% for the silted approach. These data correspond to a mean absolute percentage difference of 6.0% in Table 9.

The conclusions seem justified, therefore, that—

(*a*) The differences in model spillway profiles shown in Fig. 73 are not significant in reflecting the behavior of the prototype under conditions of free and submerged discharge; and

(*b*) The generalized relationship between submergence percentage, p, and the ratio of submerged to free discharge, $\frac{C}{C_0}$, as expressed by Eq. 27, is valid within the scatter of field observations on the prototype.

D. C. McConaughy,[26] Esq.—Mr. Warnock mentions the importance of comparing the performance of model and prototype in order to determine the extent to which the model may be relied upon for quantitative results, and comments on the small amount of progress made in this direction. As bearing on this question, the writer should like to present the following comparison between performance of a river channel improvement model having a discharge of 1.75 cu ft per sec and its prototype having a discharge of 276,000 cu ft per sec.

To prevent undesirable elevations of the backwater in the Columbia River above Grand Coulee Dam in the vicinity of the International Boundary, studies of the possibilities of river channel improvement were undertaken in 1940. Of course, these required a knowledge of backwater conditions over the entire distance of nearly 150 miles, which was obtained by computation. For improvement work, attention was concentrated on a large rapids known as "The Little Dalles," about 16 miles below the International Boundary line. Here, for a distance of about 2,500 ft, the normal channel width of about 1,000 ft is constricted to a width of about 300 ft, with a depth of about 200 ft. The flow at normal flood discharges was characterized by huge boils and eddies, the loss in head through the reach varying from a few feet for low discharge to an estimated 32 ft for the probable maximum discharge of about 650,000 cu ft per sec.

The right side of the channel at "The Little Dalles" rises abruptly; the left side levels out to a broad shelf. A large rock island, submerged at high discharges, obstructed the entrance. Near the lower end a large pinnacle of rock rose above the water surface, and at the right side a spur of rock projected into the channel, apparently causing considerable loss of head. On account of the topography and inaccessibility of the right bank, the aim was to confine excavation to the left side and to keep the bottom of the excavation above low water. The resulting enlarged channel thus would have a comparatively shallow bench, of varying width, at one side of the natural deep narrow channel. It was desired to know the effect of removal of the island to varying elevations, the effect of removal of the pinnacle and spur previously mentioned, and the effect of these on the amount of excavation required on the left bank, as well as the effect of different amounts of excavation on the losses. Some of the excavation had to be wasted in the natural river channel, if possible, to save the expense of handling. As the bottom was irregular, it was hoped this might be done without appreciable effect.

---

[26] Senior Engr., Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

The stretch of river immediately below the rapids acted as a stilling basin for the high velocities through the narrow section, and the value of the roughness coefficient to be used under altered conditions was uncertain. Also it was desired to have a check on the validity of certain assumptions as to the relation between the roughness coefficient for the channel under natural and under backwater conditions, used in computations.

A model offered the best, if not the only, means of obtaining the information desired. The channel was stable, and water-surface elevations above and below the reach were available up to a discharge of 420,000 cu ft per sec, so that the gage-discharge curves could be accepted with confidence, at least up to that discharge. Since data for discharges up to 650,000 cu ft per sec were required, it was necessary to extend the curves to that figure. The upstream curve had certain peculiarities, probably due to the effect of the island, and extensions failed to agree by several feet with an apparently reliable high-water mark. Computed water surfaces, starting from the downstream station, checked one method of extension, and the model later checked this extension to within about a foot. This elevation was very important, on account of its nearness to the boundary. There was also a gage-discharge record up to 361,000 cu ft per sec at a point slightly above the lower end of the constricted section and about halfway between the two stations, which were about a mile apart. Topography had been taken above the low-water surface, and the low-water channel had been cross-sectioned at an average interval of about 200 ft, the sections being closer together at the upper end where the section was changing fast.

Space limited the scale of the model to 1 : 120, although a larger scale would have been better. After the model was built, it was "calibrated" by roughening the sides until the model water surface agreed with the field data for the three known points. This roughening was done by adding lumps of concrete to the sides and bottom of the channel and by placing somewhat larger pieces in the shape of needles in the channel, the cross sections indicating that such formations were present in the prototype. Photographs of the river were of considerable assistance in this work. After the calibration was completed in the spring of 1940, profiles of the water surface were obtained from the field during the annual flood for discharges between 62,000 and 240,000 cu ft per sec. The agreement between these profiles and those obtained from the model was remarkable, such differences as existed being easily attributable to the effects of local conditions at the points where the field measurements were made. After the "calibration" was completed, studies of the losses through the reach for varying amounts of backwater and discharge were made for a variety of channel improvements.

As a result of the model studies, it was found that excavation of the island at the entrance for any practicable distance below El. 1,255 was ineffective; that the removal of the spur on the right side at the outlet was comparatively ineffective; that equally good results could be obtained by excavation on the left bank; that the removal of the needle was effective; that some further decrease in the loss could be effected by proper disposition of the spoil from the excavation; and that none of the spoil could be deposited in the channel without affecting the losses. It was possible to lower the water surface upstream by 7 ft at the maximum discharge contemplated (650,000 cu ft per sec), by excavation estimated at 300,000 cu yd, mostly in the left bank. Comparison of relative effects of varying amounts of excavation indicated that this was about the limit of what could be accomplished, great further increases in the amount of excavation resulting in little corresponding benefit.

Unfortunately for the purposes of this discussion, there have been no large discharges since the work was completed. However, it seems timely to give such data as have been obtained (see Table 13).

TABLE 13.—COMPARISON OF ACTUAL AND PREDICTED LOSSES, THE LITTLE DALLES CHANNEL IMPROVEMENT—COLUMBIA RIVER

Discharge, in cu ft per sec	Water-surface elevation downstream	LOSSES, IN FT		Error (ft)
		Predicted	Prototype	
94,700	1,289.93	0.90	0.83	0.07
127,000	1,287.63	1.40	1.62	0.22
144,000	1,261.93	8.00	8.06	0.06
146,000	1,288.53	1.60	1.87	0.27
188,000	1,290.53	2.45	2.91	0.46
215,000	1,287.48	3.70	4.25	0.55
217,000	1,291.89	3.10	3.62	0.52
225,000	1,270.17	9.90	10.30	0.40
235,000	1,291.96	3.70	3.81	0.11
246,000	1,273.25	9.70	10.19	0.49
247,000	1,291.06	4.30	4.70	0.40
252,000	1,277.04	8.25	8.73	0.48
255,000	1,280.62	7.05	7.29	0.24
269,000	1,285.78	6.30	6.66	0.36
273,000	1,287.90	5.90	6.60	0.70
276,000	1,288.14	5.95	6.53	0.58

The actual losses are greater than those predicted from the model, except in one case, and the difference seems to increase with increasing discharge. The variation in differences for nearly similar conditions leads to the conjecture that the average of a greater number of field observations might agree more closely with the predictions. Although, as previously stated, the model showed that no spoil should be deposited in the channel, it was not possible to keep out all the excavation. An unknown amount (probably not large, comparatively) reached the channel and, to some extent at least, the discrepancies may be caused by this fact. Model observations were made in discharge increments of 100,000 cu ft per sec, and there may be small errors due to interpolation for other discharges.

L. STANDISH HALL,[27] M. AM. SOC. C. E.—The subject covered by the Symposium is very timely and indicates the need for further study on the conformity between model and prototype. As a matter of fact, much can be learned by studying the actual operation of structures already built. The reasons for the apathy in checking the performance of hydraulic structures have been excellently presented in the paper by Messrs. Warnock and Dewey. Nevertheless, many factors entering into hydraulic design are observed best in full-size structures. These factors include air entrainment, air locking, vibration, cavitation, standing waves, wave trains, bed movement, and scour below structures. The value of photography in studying many of the phenomena needs to be stressed particularly.

---

[27] Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

Frequently papers are prepared describing in detail new construction shortly after the completion of the work, but before an opportunity has been provided to test out their actual operation. If, at a later date, it is found that changes are necessary in order to improve the operation, very often no publicity is given to these alterations, with the result that some future designer searching engineering literature for ideas may duplicate the same errors by repeating the original unsatisfactory designs. For this reason, the writer wishes to call attention to two unsatisfactory designs that have required modification.

The San Pablo Dam near Oakland, Calif., was constructed in 1917–1920 (65) and was provided with both an open-channel spillway and an auxiliary vertical shaft spillway equipped with outlet gates below full reservoir level. The horizontal leg of the shaft spillway was laid on a re-entrant grade, and a weir was built below the outlet to assure submergence of the tunnel. The idea behind this design was that a water cushion always would be provided by the 24-ft column of water impounded at the bottom of the vertical shaft. The problem of disposal of air carried by the falling water into the horizontal leg, if considered, was dismissed as not being of serious importance. In operation, it was found that small bubbles were carried down the vertical shaft and into the horizontal leg, where they accumulated in large bubbles along the roof. These bubbles moved slowly along the grade of the tunnel toward the outlet and discharged periodically with explosive violence, throwing water as spray to a height of 40 to 50 ft in the air. The vibration caused in the tunnel following each of these air discharges was also a serious problem.

A model was built of this shaft by the engineering division of the East Bay Municipal Utility District in Oakland to test the operation with valves placed at the bottom of the vertical leg which would control the opening and keep the proposed discharge outlet into the horizontal leg submerged at all times. This alteration reduced the discharge capacity of the shaft spillway, but the open spillway is of adequate capacity to carry the largest flood (66). The model was built on a 1-to-14 scale and it was found that, if the submergence of the valves was not greater than 6 ft, air bubbles, caused by the impact of the stream falling from the top of the shaft, could be carried through the water cushion into the horizontal leg of the spillway. In the prototype, this would be equivalent to a submergence of 84 ft, although it is not known whether this proportional relation between model and prototype is applicable with reference to these air bubbles. However, a submergence in the 84 ft of the prototype was entirely feasible. In the model test, air bubbles discharging freely at the tunnel outlet through the horizontal leg threw spray to a height of about 1 ft. This would be equivalent to 14 ft in the prototype, although, as previously stated, the spray actually was thrown to a height of between 40 to 50 ft in the prototype. Likewise, the mild vibrations in the model would be difficult to translate into the violent temblors of the prototype. The alteration on this structure apparently will remedy the previous faulty operation, but the tests indicate that strict conformity between model and prototype cannot be obtained under conditions of air entrainment in closed conduits.

The second structure to be considered is the tunnel spillway at the Chabot Dam near Oakland, which is one of the two spillways at this dam. This particular structure, constructed of masonry in 1889, has a side-channel spillway discharging into a tunnel. The weir at the inlet consists of three openings, each 13 ft wide, with the tunnel portal located only 10 ft from the downstream opening. The water drops 8 ft to the level floor of the channel, which merges into a transition section built on a grade of 6.1%. The tunnel is a 10-ft by 10-ft horseshoe section 1,438 ft long. Except for the entrance, the grade is 2.5%. At the tunnel outlet the waterway expands abruptly into an open masonry channel about 17 ft wide. This channel has a length of 662 ft from the tunnel outlet to the vertical overfall to the creek, and has a horizontal curve near the tunnel outlet. From this description it can be gathered that the structure violates practically every principle of modern hydraulic design for streamline flow.

The operation of the tunnel spillway under full discharge has never been satisfactory because of the poor hydraulic properties of the tunnel inlet and outlet. The weir has a potential capacity of 4,000 to 5,000 ft, but this cannot be utilized fully as the carrying capacity of the tunnel is only 2,000 cu ft per sec.

As the maximum carrying capacity is approached, the tunnel mouth is submerged, and air entrained in the water at the drop over the weir is carried into the tunnel. This air rises to the roof of the tunnel within 400 ft of the inlet, and a portion escapes through the downstream portal. A section of the tunnel, 100 to 200 ft long below the inlet, is under pressure of the air and water mixture, and, when sufficient pressure is created, a portion of the air accumulated along the roof discharges violently back through the inlet, throwing spray into the air. The water, rushing in to replace the discharging air, causes severe vibrations in the masonry of the tunnel.

Flow conditions at the outlet, at maximum discharge, also are not satisfactory. The sudden expansion of the cross section creates cross waves which overtop the walls. The horizontal curve farther downstream augments the cross waves and causes an overtopping of the walls for a second time. Water overtopping the walls of the channel does no particular damage, since the top of the wall is below natural ground surface and the water returns to the channel. Furthermore, floods of sufficient magnitude to cause overtopping rarely occur.

Normal consideration of the hydraulic conditions at the tunnel entrance would not reveal the cause of the pressure built up by entrained air at this point. With the contraction of the stream and loss of head at the portal, it would be impossible for the tunnel to flow at full capacity below the inlet, and, therefore, the air carried into the tunnel should be able to discharge freely from the lower end. The most probable explanation of the phenomenon is as follows:

1. Air is entrained by the water dropping over the steps of the entrance weir. Model experiments (67) by Julian Hinds, M. Am. Soc. C. E., on side-channel spillways indicate that a considerable volume of air may be entrained in the water below a weir. Even with the small heads used in his experiments (not more than 1 ft), the volume of entrained air was as high as 20% and averaged at least 4%. With large spillways, the entrainment naturally would be much greater than the average determined from model tests.

2. Air entrained in the water by the initial drop tends to escape, provided the velocity of the water is not sufficient to maintain the insufflation created by the drop over the weir. This would be the case above the Chabot tunnel portal, as a large part of the velocity is lost by the change in the direction of flow. However, much of the entrained air would be carried forward into the tunnel, as time would not permit the escape of much air in the short distance between the weir and the portal. In the tunnel section under capacity discharge, air entrainment or insufflation is reduced because of the small area exposed to the air. Hence, air entrained in the water tends to escape. As the water entering the tunnel will contain a considerable proportion of air in the form of bubbles, these will rise to the surface and with maximum flow will collect along the roof of the tunnel, since as soon as the mouth or portal is submerged, the upper end of the tunnel actually will be flowing under pressure. Experiments (68) by J. P. Frizell indicate the rate of rise of small bubbles in still water to be approximately 9 in. per sec.

3. The uncertainty as to the amount of air entrained in the pool below the entrance weir precludes a precise calculation of the volume of air carried into the tunnel with the water. Study of photographs taken during the flood periods in the past leads to the belief that the amount was large enough to obstruct the tunnel seriously. Assuming a 10% entrainment in the tunnel entrance, there would be a volume of 200 cu ft of air per sec at a discharge of 2,000 cu ft per sec. Air bubbles in the pool above the tunnel portal are compressed in direct proportion to their depth of submergence. Those near the bottom naturally have the greatest compression. After passing through the tunnel portal, a portion of the pressure head is converted into velocity head, and the reduction in pressure causes the air bubbles to expand, thereby increasing the air bulking. Hence, contrary to normal hydraulics the air-water mixture fills the tunnel, except for an air pocket formed below the tunnel mouth by rising air bubbles. The mixture of air and water must cause a pressure within the tunnel well past the break in grade located 50 ft from the tunnel mouth, since, as soon as a clear space is formed continuously at the tunnel roof, the air should escape at the downstream end. The air locking at the tunnel mouth must be caused by conditions in the first 50 ft or 100 ft of tunnel, since it does not seem likely, under reasonable assumption of entrance losses and tunnel friction losses, that the tunnel could flow full for its entire length even under the maximum possible reservoir elevations. As soon as sufficient air pressure has been built up in this part of the tunnel to exceed the water pressure at the portal, air escapes explosively through the tunnel entrance. The water rushing in to replace the escaped air in the tunnel creates a severe vibration of the tunnel lining. The vibration possibly could

be caused by a hydraulic jump within the tunnel. If an air bubble formed along the roof 100 ft or more from the portal, the velocity in passing this obstruction might be great enough to cause a jump to form downstream. The slope of the tunnel at Chabot Reservoir is so steep (2.5%) that under flow conditions without air entrainment a jump could not occur. The references (69)(70) for a jump in closed conduits describe tests made on conduits for slight slope or with the outlet end submerged.

4. The maximum distance that air bubbles can be carried into the tunnel before rising to the roof can be computed. The velocity of the water in the tunnel is slightly more than 30 ft per sec; hence, assuming a uniform distribution of entrained air in the tunnel cross section and assuming an average rate of rise of bubbles in water of 0.75 ft per sec, a bubble on the floor of the tunnel at the entrance will travel a distance of 430 ft from the inlet before reaching the roof. Turbulent flow existing in the water actually will vary this distance of travel, but the computation serves to indicate the approximate length of tunnel required to accumulate all of the entrained air at the roof. The free air space downstream from this point will permit escape of this air through the outlet.

The remedy directed toward the cure of the conditions of flow caused by submergence of the tunnel portal is relatively simple (although not yet effected because of the infrequency of major floods), as in this instance it is only necessary to provide gates on the entrance weir in order to preclude a discharge of water over the weir in excess of the capacity of the tunnel with free flow. However, to study more fully all of the flow problems of this structure, a model test would be very desirable.

Undoubtedly, many other structures exist which have exhibited unsatisfactory flow conditions. A study of these structures by means of models would provide better knowledge of the conditions leading to nonconformity between model and prototype. At the same time more confidence would be developed in the conditions under which model tests may be relied on for quantitative results. Finally, a better interpolation of tendencies would be indicated in the model for those factors in which the attainment of exact similitude is impossible.

A. J. GILARDI,[28] M. AM. SOC. C. E.—In a discussion of conformity between model and prototype, it is well to differentiate between generic conformity and specific conformity. The first, generic conformity, refers to the similarity of behavior, indications, and tendencies between model and prototype, whereas the second, specific conformity, refers to agreement of measured quantities and derived coefficients in accordance with the laws of hydraulic similitude. The first also might be called qualitative conformity, and, the second, quantitative conformity.

Specific conformity between model and prototype often is not ascertainable with accuracy. For instance, the prototype or improvement works may have been built differently from the model; or the conditions tested in the model may never occur in the prototype. On the other hand, accurate field measurements in the prototype may be too expensive or too impracticable to secure, and often less desirable methods or curtailed observations are substituted.

---

[28] Seattle, Wash.

In one particular experimental program, the preliminary tests of a large pump indicated that, with a special type of suction line, the output could be increased materially, especially if the diameter of the suction nipple were increased substantially. The prototype pump was built accordingly; but, unfortunately, the larger nipple was never tested in the model, and thus an excellent chance was lost to determine the specific conformity. The prototype results were very satisfactory and demonstrated the generic conformity. Incidentally, the preliminary tests alone were sufficient to secure the adoption of the formerly controversial type of suction line. In addition, the operational savings brought about by the increased diameter of the suction nipple in all probability paid for the cost of the entire experimental program in a short time.

In a broad sense, generic conformity is much easier to ascertain than specific conformity, mostly because a reasonable similarity of construction and of conditions is usually sufficient. For this reason, statements are much more frequent on generic conformity than on specific conformity, and would be still more frequent, were it not for the following peculiarity of human nature.

Men—and engineers—can learn as much by failures as they can by success. From the broad viewpoint of the engineering profession as a whole, how desirable it would be if the veil of secrecy surrounding some engineering mistakes were to be lifted just enough to prevent the recurrence thereof! Unfortunately, not much printer's ink ever will be needed for such confessions.

One or two examples will be sufficient to illustrate the point. In the case of an overflow dam, some of the experiments showed that baffle piers would be subjected to the impact of debris and to much erosion on account of the presence of cobbles and other sediment in the water. These warning indications were disregarded and the baffle piers were built, with the result that considerable damage took place in a short time.

On another project, experiments showed that a proposed layout would bring about uneven and rough filling conditions and therefore that other layouts which had performed more satisfactorily should be considered instead. However, the first-mentioned layout was adopted, and there has been trouble ever since. Again, a faulty decision!

The Symposium is a very helpful contribution to the engineering literature on the subject of hydraulic models, and it is to be hoped that many other observations on the conformity between model and prototype will be made available to the profession in the course of time. However, the writer is inclined to think that what engineers need mostly is a more discriminating attitude toward hydraulic model experiments in general.

There was a time when hydraulic experimentation was looked upon by many as mere play and when securing of funds for such work was full of endless difficulties. The pendulum has swung too far in the opposite direction since those days, and in more recent years some involved experimental programs have been conducted which either could have been omitted entirely or could have been curtailed very materially by adequate investigation and research.

Also, there was a time when the results of hydraulic experimentation were looked upon with some suspicion, but here again the pendulum has swung too far in the opposite direction; and, particularly during the last ten or fifteen years, a definite tendency to place a blind reliance on hydraulic experimentation seems to have developed. In other words, although at one time reliability was doubted by many engineers, an even greater number now take such reliability for granted.

The foregoing circumstances place a great responsibility upon hydraulic laboratories to undertake model studies only after thorough investigation and understanding of the prototype conditions and of the possibilities of reproducing them with accuracy in the model. The experimental program then should be selected and planned for the sole purpose of securing the required results with a minimum of time and expenditure and with elimination of all superfluous or duplicating data. Finally, great care should be exercised in the analysis of the results, formulation of conclusions, and presentation of recommendations. The most important phases of this work should be handled by engineers with practical experience and mature judgment.

The project engineers, or consulting engineers as the case may be, should never forget that the ultimate responsibility for the success or failure of the project is theirs, and should not permit their judgment to be swayed by pet ideas of their own or of some influential fellow engineers. These men should have a good working knowledge of hydraulic models and a realization of the limitations of such work, and should retain at all times the perspective of the ultimate goal to be attained. They should make sure that the hydraulic laboratory has understood and reproduced the prototype conditions and analyzed the results of the tests properly. Such warning indications as might have turned up during the experimental work should be taken into consideration.

Some of the remarks in the preceding paragraph may seem quite obvious and somewhat superfluous, but engineers with extensive practical experience and with understanding of human nature probably will recall examples to which some of the foregoing statements apply readily.

The field of hydraulic experimentation is very broad and extremely varied; as such, it has many pitfalls. In some unusually complex situations, the laboratories at which work was conducted failed to understand the prototype conditions, then the laboratories proceeded to formulate and conduct the experimental programs under conditions different from the significant ones, which of course led to wrong conclusions. In view of the aforementioned tendency to take the laboratory data at face value, satisfactory solution of such situations has been delayed by many years—if not prevented entirely—through the confusing and harmful influence of such hydraulic experimental work.

Hydraulic experimentation is an excellent tool for the solution of problems that cannot be approached satisfactorily in any other manner. However, it should be undertaken only after careful preliminary research, and then it should be prosecuted with meticulous care to its completion and should not be stopped before the best results are secured.

Experience with hydraulic models shows that conformity between model and prototype already is well demonstrated and that engineers should focus their attention much more on both careful planning and execution of hydraulic experimentation and correct application of its results to the prototype.

Fred W. Blaisdell,[29] **Jun. Am. Soc. C. E.**—This Symposium on the conformity between model and prototype will serve partly to fill the need for quantitative data on this subject. As stated by Messrs. Warnock and Dewey (see heading, "Introduction"), qualitative data, even though the comparisons are excellent, do not have quite the value to persons not associated closely with a specific project as do quantitative data. It is to be regretted that several of the prototypes discussed in the Symposium were not geometrically similar to their models. However, the results presented for even these structures are of considerable value in spite of the fact that, in some cases, the geometrical discrepancies are large enough to account for the lack of conformity.

In 1939, at the Hydraulic Laboratory of the National Bureau of Standards, Washington, D. C., the writer tested several models of combination Parshall flume and shallow Columbus-notch measuring devices installed by the Soil Conservation Service on the Blacklands Experimental Watershed near Waco, Tex. (71). In this discussion, the results of the tests on Parshall flumes are compared with tests (72)(73) made by R. L. Parshall, Assoc. M. Am. Soc. C. E. The only comparisons possible for the Columbus notches are between the full-size and half-size models.

Description of Parshall Flume Models.—The models (see Fig. 77 for drawings of a typical model) were made of concrete, the surface of which was painted with neat cement mortar after stripping the plywood forms. All inside surfaces were polished with a carborundum brick after the mortar had hardened. The same Parshall flume floor, crest, and false approach floor were used for all models, new walls being cast to give the desired model dimensions. Dimensions of the models tested, corresponding to those shown in Fig. 77, are presented in Table 14.

Head and Discharge Measurements.—Head measurements, at the points indicated in Fig. 77 and Table 14, were made to 0.0005 ft with point gages. In addition, water-level recorder data ordinarily were obtained for each run. The recorder charts were read to 0.001 ft, and the readings were corrected for instrumental errors, line shift, and paper expansion before being compared with the point gage readings. The agreement between point gages and water-level recorders was ordinarily better than 0.005 ft. However, the water-level recorder readings were used mainly to determine average heads when erratic or long-period fluctuations of the water surface occurred.

Discharge measurements were made—

With a:	For a discharge (in cu ft per sec) between:
⅝-in. water meter	0.007 and 0.06
Venturi meter in a 1.5-in. line	0.06 and 0.17
Venturi meter in a 4-in. line	0.06 and 0.57
Venturi meter in an 8-in. line	0.57 and 3.5
8-ft rectangular weir	0.43 and 35

—the combined capacity of the available pumps. Water passing through the 1.5-in. venturi meter also passed through the 4-in. venturi meter; all water passed over the 8-ft weir. When possible, rates of flow were frequently measured with two measuring devices. All measuring devices were calibrated in place several times, the water meter and venturi meters being accurate to ± 1% and the weir to ± 1.5%.

Tests on Parshall Flumes.—Two full-scale models of the 6-ft Parshall flume were tested; 97 tests were made on the first model and 38 tests at low heads on the second model. The capacity of the laboratory pumps would not permit testing the full-scale structure at its maximum design head, and half-scale models were tested principally to obtain the upper end of the rating curve. The full-scale tests were made to define the rating curve for the lower heads where viscous and surface tension forces have the greatest influence. The number of tests run on the half-scale model of the 6-ft Parshall flume was 255. The number of tests made on all three models of the 6-ft Parshall flume was 440. A total of 131 tests was made on a 1 : 3 scale model of a 10-ft flume, and 127 tests on a 1 : 5 model of a 15-ft flume. Mr. Parshall has reported in the Bibliography (72)(73) the number of free-flow tests, for these flume sizes, as 35, 19, and 4, respectively.

Parshall Flume Rating Curves.—The results of the tests by both Mr. Parshall and the writer are presented in Fig. 78. Data points for many tests on the 6-ft Parshall flume were omitted for the sake of clarity, as noted in Fig. 78(*a*).

The Parshall flume curves drawn in Fig. 78 and based on the model experiments have the equations:

For the 6-ft Parshall flume,

$$Q = 24.6\ (H_A)^{1.577} \ldots\ldots (29a)$$

for the 10-ft Parshall flume,

$$Q = 40.9\ (H_A)^{1.59} \ldots\ldots (29b)$$

and, for the 15-ft Parshall flume,

$$Q = 61.5\ (H_A)^{1.59} \ldots\ldots (29c)$$

in which Q is the discharge in cu ft per sec and H_A is the free-flow head measured in the stilling well in feet. These equations represent the experimental data, with few exceptions, to within ± 1% above heads of 0.05 ft. Corresponding equations developed by Mr. Parshall from his tests are, respectively:

$$Q = 24.0\ (H_A)^{1.595} \ldots\ldots (30a)$$

$$Q = 39.38\ (H_A)^{1.6} \ldots\ldots (30b)$$

and

$$Q = 57.81\ (H_A)^{1.6} \ldots\ldots (30c)$$

The curves represented by these equations are also shown in Fig. 78.

The agreement between the model tests made by the writer and the data obtained by Mr. Parshall is presented in Table 15. The agreement of Mr. Parshall's data with his equations developed therefrom also is presented for purposes of comparison.

Several interesting speculations can be made in regard to the data presented in Table 15. In regard to the observed discharges, Mr. Parshall states that current meters were used for the 10-ft and 15-ft flumes and standard 10-ft or 15-ft rectangular weirs for the 6-ft flume. Mr. Parshall also states (73*a*) that "The probable error of individual current-meter measurements * * * is from 2 to 3 percent." It is probable that no greater accuracy can be expected from standard weirs that have not been calibrated. Errors, probably systematic, of this magnitude therefore must be expected in the equations presented by Mr. Parshall. On the other hand, discharge measurements by the writer were made by means of devices calibrated by weight measurement of the discharge and are accurate to within ± 1.5%. It appears, therefore, that the average differences between Mr. Parshall's data and the equations developed by the writer are not greater than reasonably can be expected.

The test data obtained by the writer are plotted in Fig. 78. The excellent agreement between the plotted data and the equations determined therefrom is readily apparent, even at prototype heads as low as 0.05 ft for the 6-ft flume (half-scale model head = 0.025 ft) and 0.06 ft for the 10-ft and 15-ft flumes (10-ft flume, third-scale model head = 0.02 ft; 15-ft flume, fifth-scale model head = 0.012 ft).

Data for both full-scale and half-scale models of the 6-ft flume are presented in Fig. 78(*a*). It will be noted that both full-scale and half-scale model data plot on a single curve even at prototype heads as low as 0.013 ft, although the scatter is high at the lower heads. The agreement between full-model and half-model tests and the equation of the average curve, with few exceptions, is better than ± 1% for heads greater than 0.05 ft.

It is interesting to speculate on the comparison of the writer's model tests, made in a laboratory, where carefully calibrated measuring devices were available, with Mr. Parshall's tests, which were made in the field with less accurate measuring devices. It seems reasonable to assume that in this instance the model tests, made in the laboratory where a high degree of precision is obtainable, give better results than prototype field tests made under conditions permitting less precision in the measurements. This same thought has been stated by Messrs. Warnock and Dewey in this Symposium (see heading, "Factors Making Comparisons Difficult").

Mr. Parshall mentions (72*a*) a depression in the water surface over the stilling-well entrance for the 6-ft flume, caused by water flowing past the contractions at the upstream end of the converging section, which he estimates to be 3 in. for discharges of 75 to 85 cu ft per sec. This phenomenon was observed for the half-scale model and, for a discharge of 139 cu ft per sec, caused a depression amounting to 2.5 in. in the prototype. However, the depression in the head observed in the stilling well was only 0.051 ft.

Description of Columbus-Notch Models.—The shallow Columbus notches are used in the field for measuring discharges less than those that can be measured accurately by the Parshall flumes. A typical installation is shown in Fig. 77, this particular installation being the only one on which both full-scale and half-scale model tests were made. The notches were pre-cast and stored until needed in the model. After curing, the notches were polished with a carborundum brick. Wall and approach floor construction was similar to that for the flume. Reference is made to Fig. 77 for details of the installation.

Tests on Columbus Notches.—In all, 73 free-flow tests were made on the full-scale Columbus-notch model and 140 tests on the half-scale model. Because of the sloping floor of the Parshall flume throat and the short distance between this throat and the Columbus notch, there were intense eddies which produced poor flow conditions approaching the notch. Thus, the heads

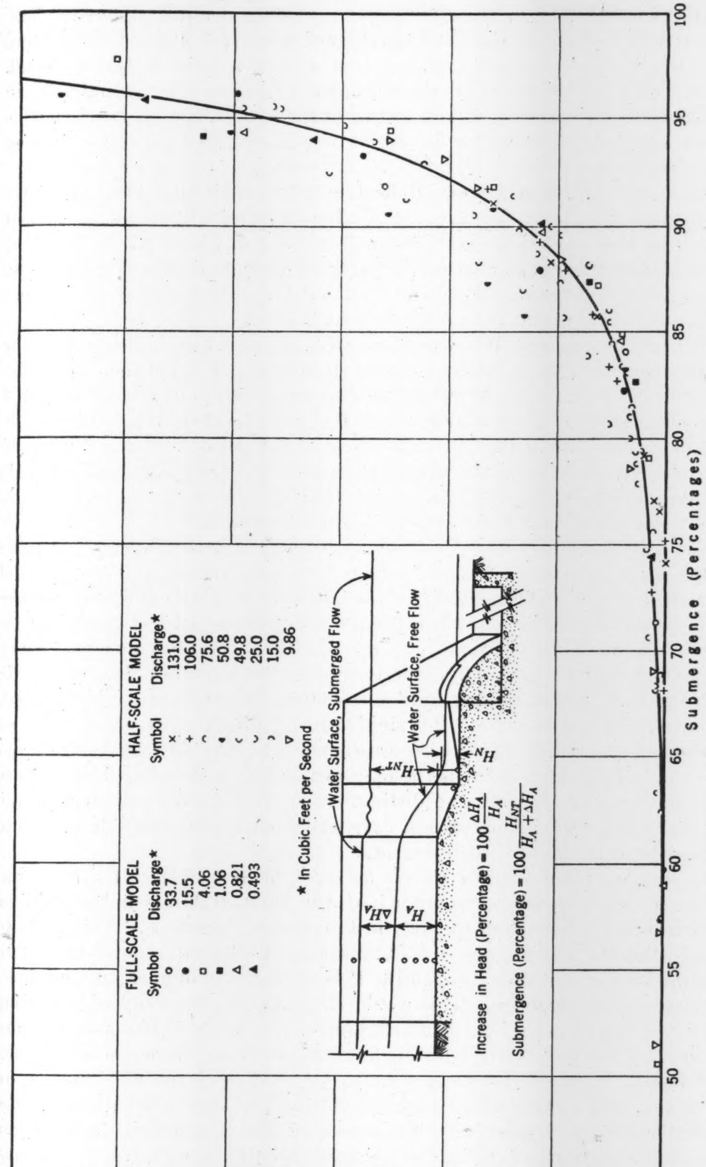

FIG. 79.—PARSHALL FLUME SUBMERGENCE CURVE FOR 6-FT PARSHALL FLUME

fluctuated considerably in the stilling wells, making readings difficult. The piezometer for measuring the head on the notch is very close to the sloping floor of the Parshall flume throat and just around a bend in the side-wall. The water at this piezometer is very turbulent and any slight dissimilarity in the positions of the standing waves, whirls, or the hydraulic jump, between the full-scale and half-scale models would have a large effect on the measured head at the notch.

Columbus-Notch Rating Curves.—The data obtained on these two Columbus-notch models are presented in Fig. 78(*d*). It will be noted that the agreement between the two models is excellent up to a head of about 0.3 ft, but that beyond that point the agreement is poor. Although it is not possible to explain all of the differences fully and with certainty, data were obtained that provide a plausible explanation for some of them.

Observations made at Waco on the prototype structure indicate that the pool upstream from the notch washed out (that is, the flow between the notch and the flume throat changed from streaming to shooting) at a head of 0.45 ft on the rising stage and filled in again at the same head on the falling stage. The pool washed out in the full-scale model at a head of 0.48 ft, which is in reasonable agreement with the value observed in the field. In the half-scale model the corresponding prototype head is 0.34 ft. The following explanation may have some bearing on the reason for this discrepancy:

From a study of the water-level recorder charts, it is possible to determine that the discharge was increased from test to test for the full-scale model and decreased, with one exception, for the half-scale model. The fact that the flow was increased from test to test for the full-scale model and decreased for the half-scale model may explain why the two curves do not coincide. Additional weight is given to this hypothesis because, for one run on the half-scale model, the flow was increasing until just before the readings were obtained. The datum point plotted from this single run (Q = 5.82 cu ft per sec) agrees with the full-scale data, which also were made with the flow increasing from run to run. This single point is the only available evidence on which to base the conclusion that separate and distinct rating curves exist over part of the range for rising and falling stages. No other data are available either to substantiate or to refute this statement.

Comparison of Submergence Curves for 6-Ft Parshall Flume Models.—Continuous records of stage are made for both the Parshall flumes and the shallow Columbus notches in each of the field installations of this type. This leads to the suggestion that the stage records obtained for the Columbus notch be used to determine whether the flow through the Parshall flume is submerged, and, if so, the degree of submergence. This would eliminate the necessity of providing a third recording gage at each installation to record Parshall's submergence head H_B. Therefore, tests with high tailwater levels were made on each model tested. Since full-scale and half-scale models of the 6-ft flume were constructed and tested under submerged conditions, a comparison of the submergence curves is possible. The results of 30 full-scale and 78 half-scale model tests are presented in Fig. 79. Special attention is called to the method of computing the percentage increase in head, which can result in increases in head greater than 100%. This method was used to simplify the computations for the submergence correction curves prepared for each installation tested. It will be noted that there is considerable scatter to the data, but that data obtained from either model can be used to define the curve shown.

Discussion of Discharge Computations for Submerged Flow Conditions.—The method of computing the discharge for submerged flow presented by Mr. Soucek (see heading, "Comparison of Model and Prototype") can be shortened considerably and all trial computations eliminated if his family of submergence curves is replaced by an average submergence curve. The maximum indicated error in discharge as a result of this substitution is only ± 3% up to a submergence of 85%. Above this submergence, the submergence curves are steep, and small errors in determining the submergence result in large errors in the submerged discharge correction. This makes the increase in accuracy as a result of rising multiple submergence curves rather fictitious, from a practical standpoint at least. The resulting simplification in computing the discharge is considerable, since trial computations are unnecessary and it is unnecessary to estimate the discharge before beginning the computations. This method was used by the writer in computing submergence correction curves for the Parshall flumes discussed herein.

A. R. THOMAS,[30] ESQ.—This subject has received considerable attention in India from the Central Board of Irrigation and its Research Committee. There is general agreement on the great value of model experiments, but it is recognized that, from the aspect of accuracy of reproduction of prototype conditions, models are of different types.

Models of rigid structures, without erodible boundaries and in the absence of sediment transportation, can give highly accurate results although there are cases in which allowance is required for scale effect. For example, experiments with models of high-coefficient spillways (74) showed considerable scale effect despite moderately high Reynolds numbers, presumably because of the influence of viscous shear in the sharply curved non-turbulent stream. Expanding flow is another example—an expansion which is satisfactory in a model is not necessarily so in the prototype.

In cases of scour due to flow patterned mainly on the shape of rigid structures (for example, scour downstream of weirs), the results obtained have been sufficiently accurate to have comparative and quantitative value.

River models are in another category, however, for two reasons: (1) General quantitative accuracy is unattainable with present technique, and (2) because of the complexity of conditions (for example, the variation of quantity of transported material with discharge and time), the accuracy of results obtained depends largely on the design of the model and the way in which the experiments are conducted. C. C. Inglis, M. Am. Soc. C. E., has referred to mobile models (75) as "a valuable aid to engineering skill, which however they can never replace." The value of such models has been proved by the number of successful investigations in which river models played a major part.

It is not possible to give details of results obtained, but papers and discussions on the subject have been published in the Central Board of Irrigation Annual Reports for the years 1939–1940, 1941, and 1942 (79).

[30] Secy., Central Board of Irrigation, Simla, India.

Gilbert H. Dunstan,[31] **Assoc. M. Am. Soc. C. E.**—The various papers of this Symposium provide a valuable contribution to the literature of model testing. Time limitations in the teaching of hydraulics in most colleges, however, prevent more than a passing mention of the subject, except in advanced courses. Nevertheless, the writer believes that it is desirable to introduce model testing to students taking hydraulic laboratory work, and to call their attention to the various papers that have been published.

Since the value of a model depends largely upon the use that can be made of the results obtained from it, a practical demonstration will do much to convince students of the importance, validity, and limitations of model studies. This may not always be possible in a college laboratory, although the following arrangement has provided one solution at low cost.

Several years ago a standard 1-ft Parshall flume was constructed in the Hydraulics Laboratory at the University of Alabama, at University. It was made of timber, lined with sheet metal. The water supply available does not permit the calibration of the flume at rates of flow greater than about 1.5 cu ft per sec. It would be desirable to have at least twice this amount for the highest point on the calibration curve for this flume.

Subsequently, a small sheet metal flume was made with a 2-in. throat, or one sixth the prototype size. This can be calibrated over a wide range of flows. Students calibrate both the prototype and model flume. From the model data and the geometric scale ratio, the head for the prototype is obtained, and the prototype discharge is obtained from the model discharge by multiplying by $(L_r)^{2.5}$. The measured prototype data are plotted on a graph sheet, after which the prototype values computed from the model points are plotted.

Results obtained to date have shown good conformity, some students drawing only a single line to represent all points, whereas others represent the results by parallel lines, close together. In general, one or more model points, for the lowest flows, will be completely out of line. Computations show that, in the actual model test, the flow for these cases was laminar, whereas in the prototype it would be turbulent. This study, therefore, has been of value in demonstrating to students that a model may be used to predict prototype performance, provided that model laws and limitations are applied properly.

Robert F. Kreiss,[32] **Jun. Am. Soc. C. E.**—The data from model and prototype on the locks discussed in this Symposium not only offer model-prototype comparisons but are useful to designers of navigation locks. The writer regrets the brief mention of dynamic head and overtravel and the omission of any description of apparatus for testing prototype locks.

The difficulty of comparing culvert systems in which port designs differ is appreciated. Lock coefficients vary not only with different port designs but with aggregate port area per culvert. Differences in coefficients for model and prototype are not unexpected for the first locks and the third locks (see Table 3), inasmuch as, in the first locks, the throat area of most of the prototype ports is symmetrically larger than in the model and, in the third locks, the area of the lock chamber end of each prototype port is larger. Coefficients are in good agreement in the single comparison having geometric similitude of manifold systems.

---

[31] Associate Prof., San. Eng., Univ. of Alabama, University, Ala.

[32] Omaha, Nebr.

The effect of difference in port design on discharge capacity is clarified to some extent by the realization that lock coefficients for a single port design vary with the ratio of cumulative port area to culvert area. A relationship has been reported (76) wherein the lock coefficient, determined either as described in the paper or as an average of ten short intervals of a lockage, varies linearly on a semilogarithmic graph with the area ratio in the range from 0.89 to 2.38. The relationship is

$$C_l = \frac{\beta}{10^{\mu x}} \qquad (31)$$

in which C_l is the lock coefficient based on the exit area of all ports, x is the ratio of cumulative port exit-end area to culvert area, and β and μ, equaling 1.0 and 0.15, respectively, are constants for a lock-filling operation. The lock coefficient decreases from 0.73 to 0.44 over the range of area ratio. Differentiation gives

$$\frac{dC_l}{C_l} = \mu \log_e 10 \, dx \qquad (32)$$

This expression would be of use not only in evaluating changes in C_l resulting from small changes in area ratio for a given port design but also in approximating changes in C_l resulting from minor changes in port design if, by additional tests, the μ-values for each new design were found not to depart greatly from 0.15.

Eq. 31 is useful in a second and more important analysis. The lock coefficient, when computed from test data of short time intervals following the culvert valve opening, substantially eliminates the dynamic head effect. Consequently, Eq. 31 can be introduced into a steady flow discharge equation, as follows:

$$Q = \frac{\beta}{10^{\mu x}} A_p \sqrt{2gh} \qquad (33)$$

in which A_p is the summation of port area. From Eq. 33 it can be shown that the area ratio, at which percentage changes in either port area or culvert area are equally effective in changing the discharge capacity, is

$$x = \frac{1}{2 \mu \log_e 10} \qquad (34)$$

From Eq. 34, note that the area ratio is 1.45 when μ is 0.15. A percentage change in culvert area becomes increasingly more effective on discharge capacity as the area ratio progressively increases above 1.45. For example, the culvert area is twice as effective as the port area when the area ratio is 1.93. With area ratios less than 1.45, the culvert is less effective than the ports.

The venturi-type port design, to which Eq. 31 applies, has a throat area 51.8% as large as the exit-end area. The ratio of total throat area to culvert area is 0.75 when the area ratio x is 1.45. The area ratio is 1.93 when the total throat area is the same as the culvert area.

Eq. 34, which is applicable to manifold systems satisfying Eq. 31, is sufficient proof that the minimum flow area in a manifold system need not be the major control area for discharge. Furthermore, the shifting from port area to culvert area, as the minimum flow area passes from ports to culvert or at any area ratio, is not advisable in computing coefficients, since each area—culvert, total port throat, or total port exit (for flared ports)—provides some degree of control on discharge. Coefficients throughout the range of area ratio should be expressed in terms of one area, say that of the culvert, with a qualifying expression regarding area ratio, as $C_l = 0.62$ at $x = 1.50$.

The development of expressions comparable to Eq. 31 is needed. The exponential function is suitable probably for venturi-type ports in a manifold system but may not be applicable for square-cornered ports. For systems satisfying Eq. 31, the constants β and μ are of greater interest than the variable C_l. Their determination is difficult in prototype lock tests because of the requirement that the area ratio be changed. In model tests their measurement is made more easily.

The writer agrees with the Symposium authors that inclusion of dynamic head effects in discharge coefficients is satisfactory in model-prototype comparisons. For design purposes coefficients eliminating dynamic head effects are preferred.

J. H. DOUMA,[33] JUN. AM. SOC. C. E.—Interesting results and useful hydraulic data on problems in the field of model-prototype conformity that are not clearly understood generally by hydraulic engineers are presented in the papers of this Symposium. The first paper, entitled "Hydraulic Structures," is especially valuable to future conformity studies because of its comprehensive outline of the factors that make satisfactory model-prototype comparisons difficult. Future investigators will do well to use this outline as a guide in developing testing techniques and in eliminating experimental errors.

The results of the qualitative model-prototype comparison, described by Messrs. Warnock and Dewey, together with results of other similar comparisons appear to support the conclusion that qualitative model studies, conducted under the present-day technique, are reliable in predicting many prototype conditions with a satisfactory degree of accuracy. Quantitative comparisons, however, have frequently shown wide differences in model and prototype results. The explanation undoubtedly is that satisfactory quantitative comparisons require more exact reproduction of the hydraulic phenomena involved to make possible accurate predictions of pressures, velocities, water-surface profiles, depths of scour, and discharges.

Discrepancies in quantitative model-prototype comparisons often have been explained as due to the lack of strict dynamic similarity, when usually other factors are the chief sources of error. Frequently, the statement is made that Reynolds' criterion has not been satisfied; and that, therefore, prototype quantities are not predicted accurately by the model. Messrs. Warnock and Dewey use this reason to explain the differences in model and prototype pressures and discharges of the 102-in. outlet conduit.

Many large-scale models do not require strict compliance with Reynolds' law. Under conditions of fully developed turbulent flow in a model, or prototype, the friction coefficient is constant for any one roughness value and independent of viscosity. Therefore, model-prototype comparisons do not require compliance with Reynolds' criterion when the model scale and roughness are selected so that the friction coefficient in the model and prototype is equal and so that fully developed turbulent flow occurs in both model and prototype. A brief review of the laws of similitude will assist in clarifying the limitations of model-prototype comparisons.

---

[33] Hydr. Engr., U. S. Engr. Office, Los Angeles, Calif.

For a model to be a true representation of its prototype in every sense, both geometric and dynamic similarity must exist at the same time. Geometric similarity of the solid boundaries, including the roughness, sets the conditions for geometric similarity of the flow stream lines. Dynamic similarity of the exerting forces, and thus similarity of the fluid properties, sets the conditions for similarity of the flow characteristics. Geometric similarity is obtained by fixing all model dimensions in some direct scale ratio to corresponding prototype dimensions. Strict dynamic similarity, however, is not obtained so easily as every dimensionless parameter referring to the flow characteristics in the model must have the same numerical magnitude as the corresponding parameter referring to the prototype. In other words, the flow characteristics will be similar if the fluid properties are such that the gravitational, viscous, capillary, and elastic forces bear the required relationship of model to prototype (57*a*).

The basic dimensionless parameters pertaining to the action of weight, viscosity, surface tension, and elasticity are known, respectively, as the Froude, Reynolds, Weber, and Cauchy numbers:

$$\mathbf{F} = \frac{\rho\, V^2}{\gamma\, L}\,;\ \mathbf{R} = \frac{V\, L}{\mu\, \rho}\,;\ \mathbf{W} = \frac{\rho\, V^2\, L}{\sigma}\,;\ \mathbf{C} = \frac{\rho\, V^2}{E}$$

in which $\mathbf{F}$ = Froude's number; $\mathbf{R}$ = Reynolds' number; $\mathbf{W}$ = Weber's number; $\mathbf{C}$ = Cauchy's number; V = mean velocity; L = a length (diameter for pipes and hydraulic radius for open channels); γ = specific gravity; ρ = density; μ = viscosity; σ = surface tension; and E = elastic modulus. The magnitude of these numbers, assuming geometric similarity, must be equal in model and prototype to attain complete similarity.

When more than two of the force properties of a fluid appreciably influence some phenomenon of flow it is impossible to obtain significant quantitative observations from a model. Therefore, it is necessary to eliminate at least all but two of the force properties in order to make a model test.

For all practical purposes, elastic forces may be ignored in the usual model study, since both model and prototype are assumed to be rigid and the elastic properties of the model and prototype fluids are identical when the same fluid occurs in the model and prototype. Also, capillary forces need not be considered unless the model is extremely small and surface tension forces are appreciable.

The Froude and Reynolds criteria for similitude remain to be considered. Although both criteria cannot be satisfied when the same fluid (water) occurs in the model and prototype, it is possible to select a different model fluid with kinematic viscosity such as to satisfy both criteria at the same time. In practice, however, it is desirable to use water as the model fluid. Satisfactory model tests can be made with water when either the viscous or the gravitational forces are predominant and all other forces are of secondary importance. The proper law for similitude would be that corresponding to the predominant force.

A criterion from which to determine when Reynolds' law must be satisfied can be developed from the experiments of J. Nikuradse (59) on pipes. In his experiments the relationship between the friction factor f, as defined by the Weisback formula

$$h_f = \frac{f\,L\,V^2}{2\,g\,D} \qquad (35)$$

and the Reynolds number was determined for flow in pipes. Typical plots of the relationship are shown in Fig. 80. It is noted that for laminar flow a small change in Reynolds' number results in a large change in the friction factor, whereas for large Reynolds numbers with fully developed turbulence and for a constant boundary roughness there is no appreciable change in the friction factor for a wide range in Reynolds' number. Thus, when laminar flow exists in either the model or the prototype, Reynolds' law must be satisfied. On the other hand, when fully developed turbulent flow exists in both the model and prototype and the model scale and roughness are such that the friction coefficients are nearly equal, then the viscous forces would have a minor influence on similitude and Reynolds' law need not be satisfied.

Nikuradse's experiments on pipes revealed that the lower limit of Reynolds' number for which fully developed turbulent flow occurred varies with the boundary roughness. Fully developed turbulence existed for all of the roughness values tested when the Reynolds number exceeded one million. For the maximum roughness tested, fully developed turbulence existed for a Reynolds number of 13,000.

Based on the results of Nikuradse's experiments, a straight line, representing the lower limit of Reynolds' number at which fully developed turbulence occurs in pipes, was drawn in Fig. 80. For purposes of discussion, it is assumed that the lower-limit line extends to an f value of 0.005 as shown in Fig. 80. Additional tests on larger and smoother pipes than those tested by Nikuradse would be required to verify the assumed extension.

By plotting, in Fig. 80, the model and prototype test results for the 102-in. outlet conduits reported in the paper, it is shown that fully developed turbulence existed for all of the model and prototype tests, except for two of the model tests which plot in the transition region from laminar flow to fully developed turbulent flow. Furthermore, the values of the friction coefficients in the model tests were two to three times those in the prototype. Under these conditions, viscous forces should not be neglected since they affect similitude appreciably. Better agreement between model and prototype tests for the 102-in. outlet conduits probably would have been obtained had the model scale been larger and the model surfaces smoother.

Based on the satisfactory model-prototype comparisons for the outlet conduits reported in the paper, it appears that, for purposes of design, strict compliance with Reynolds' law is not required. Strict compliance is probably required, however, when a discharge rating curve is to be predicted accurately by a model. Study of additional model-prototype comparisons will be required to determine the limitations as to when and to what degree Reynolds' law need be satisfied.

For comparison with the lower limits of Reynolds' numbers for fully developed turbulence in pipes a similar curve for open channels is shown dotted in Fig. 80. Until more reliable limits are established, these limiting lines may be used by model designers to check model requirements with regard to Reynolds' law. For example, if a proposed model is so small that test points would plot to the left of the appropriate limiting line, then Reynolds' law should be considered.

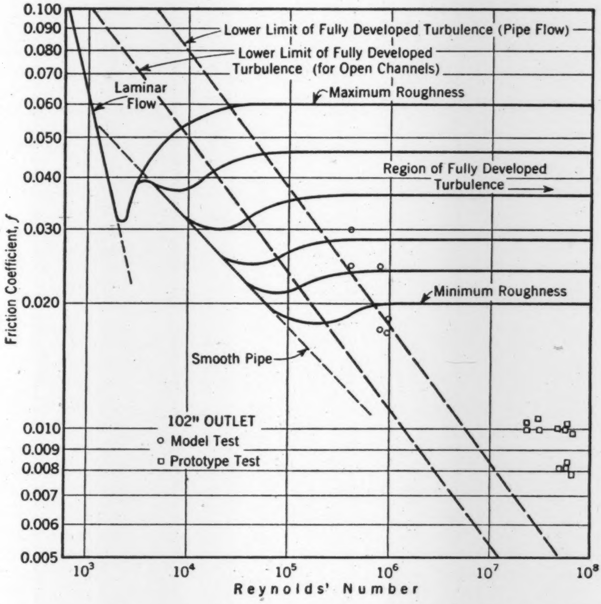

Fig. 80.—Reynolds' Number Vs. Friction Coefficient—Typical Curves for Pipe Flow

With reference to open channels, the laws pertaining to viscous forces are not well defined, and it is necessary to base an analysis of open-channel flow on the established laws for pipe flow. The Reynolds number for open-channel flow is determined by the same expression as that for pipe flow except that the hydraulic radius is used as the linear dimension instead of the pipe diameter. Therefore, Reynolds' numbers for flow in open channels, under conditions of equal velocities and hydraulic radii, will be one fourth the Reynolds numbers for pipes, since the hydraulic radius of a pipe is one fourth the pipe diameter. Accordingly, the limiting line for fully developed turbulence in open channels was drawn with values of Reynolds' numbers equal to one fourth the limiting values for pipes.

SKETCHES OF INSTRUMENTS

unusual difficulties. This was especially true of the apparatus used in the prototype tests discussed in the paper by Messrs. Nelson and Hartigan, and it is regretted that their paper did not include a brief description of the apparatus.

The authors have based their comparisons on results of stage tests and port velocity tests. Stages in a lock chamber during filling and emptying operations can be measured with apparatus of relatively simple design. However, accurate measurement of velocities of the magnitude estimated and under the conditions prevailing in lock chambers with extremely high lifts was without known precedent. Although other methods of discharge measurement were considered, the selection was reduced to the current meter and pitot tube.

In their discussion on port velocity tests on the first lock, the authors state that during a filling operation discharge through ports 1 and 3 was reversed, flowing from the lock chamber into the culvert. During the operation of the tests on some of the other locks, it was observed that the direction of flow changed frequently and rapidly during the filling operation. This condition was anticipated and was one of the principal reasons why current meters were not adopted; namely, they would not respond quickly to velocities changing rapidly in both direction and intensity. Also, current meters would offer considerable restriction to the flow if velocities were measured simultaneously at several points in the port.

Because the distance from the point of measurement to the point of observation greatly exceeded the barometric head, the pitot tube could not be used in its usual form. Since compressed air was a suitable medium and since all locks were equipped with compressed air, it was selected as the transmitting medium.

Diagrammatic sketches of the instruments used are shown in Fig. 81. Velocity heads were observed on manometers placed on top of the lock-wall. A manometer with connections for port velocity tests is shown in Fig. 81(*c*). Mercury was used in the manometers for the higher range of velocities; bromoform was used for consistently low velocities where deflection of a mercury column was insufficient for accurate readings.

The pitot bar (Fig. 81(*c*)) was equipped with piezometers for simultaneous readings at three points in the flow area. The bar offered a minimum of restriction to the flow through the lock-chamber ports and could be supported rigidly by an aluminum frame anchored to the lock-chamber wall above the lower pool water line.

The pitot bar was not calibrated before the tests were made. A coefficient of unity was used until all tests were completed. Then the coefficient of the bar for each lock was computed by correlating port velocity and lock-chamber stage measurements. The average coefficient of 0.84 was obtained from the data of all locks tested for both filling and emptying operations.

The manometers, with slight changes in connections and arrangement (Fig. 81(*b*)), were used for measuring stages in the lock chamber. If current meters had been used, one set of instruments would have been required for the port velocity tests and an entirely different set for the stage tests.

One major change in the apparatus was found necessary after the tests were started: Proper adjustment of the air supply could not be obtained with the $\frac{1}{8}$-in. needle valves. The difficulty was overcome by the installation of a 0.016-in. orifice in each connection between the air-pressure manifold and the individual manometers. This arrangement was very satisfactory and permitted considerable latitude in air pressure without affecting the readings observed on the manometers.

MARTIN E. NELSON,[35] M. AM. SOC. C. E.—The conclusions reached by Mr. Soucek, in his study of the effect of submergence on the flow of water over a spillway and in his comparison of discharge over a model crest and its prototype, are verified substantially by similar tests conducted under the supervision of the writer in 1932. The model tests in question were made in connection with the design of the spillway described in the paper by Mr. Hopkins. The tests were made primarily for the purpose of developing a stilling basin to protect the downstream toe of the dam. Two model spillway crests with cross sections as shown in Fig. 82 were constructed of concrete to dimensions $\frac{1}{20}$ as large as the proposed prototype. Model crest No. 1, simulating the original proposed design, was equipped with several pressure piezometers along its center line. On this model it was observed that, under certain conditions of discharge and head, considerable negative pressure formed under the nappe. A model of crest No. 2 was tested to determine the effect of the indicated modification in shape on the pressure gradient under the nappe. Although the pressure condition was considerably improved, for economic reasons and because the condition under which the negative pressures in the prototype might be serious would be of short duration, this design was not adopted for the prototype. However, the calibrations of model crest No. 2 will be introduced in this discussion to indicate the change in discharge coefficients for free and submerged conditions with respect to crest profile. The prototype spillway was constructed to the section designated as crest No. 1 in Fig. 82, except that the crest elevation is 737.5 instead of 736.0. The spillway as constructed is 551 ft long.

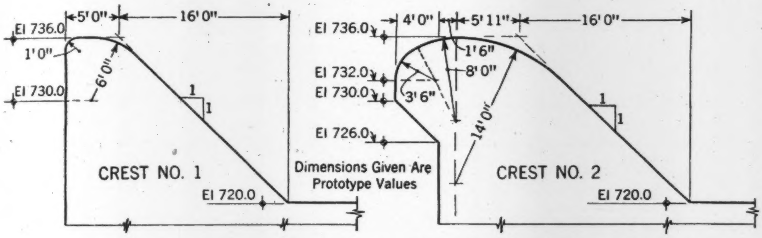

FIG. 82.—HYDRAULIC MODEL TESTS, 1 : 20 SCALE MODEL

The models, 2.53 ft long, representing spillway lengths of 50.6 ft, were tested in a glass-walled flume. The floor of the upstream approach was fixed at El. 718.0 and that of the downstream approach at El. 719.0. The water supply was measured over a V-notch weir, and tailwater levels were regulated by means of an adjustable gate at the lower end of the testing flume. Water-surface elevations in the upper pool were observed by means of a piezometer in the flume wall, together with a stilling well and hook gage, at a point corresponding to 142 ft upstream from the crest, and similar readings in the lower

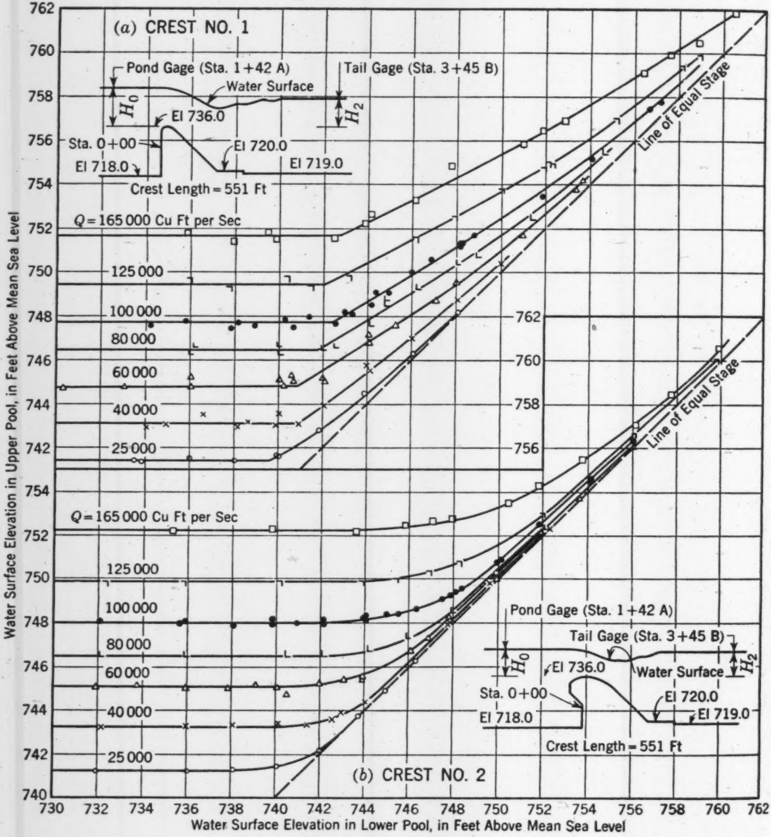

FIG. 83.—STAGE RELATION CURVES

pool were made at a distance of 345 ft downstream from the crest. In a typical test the water supply in the model was adjusted to provide a discharge corresponding to $\frac{50.6}{551}$ times an arbitrarily selected quantity of river discharge. When the flow had become steady and the tailwater level had been adjusted to a desired elevation, several readings were made on the weir gage and on the

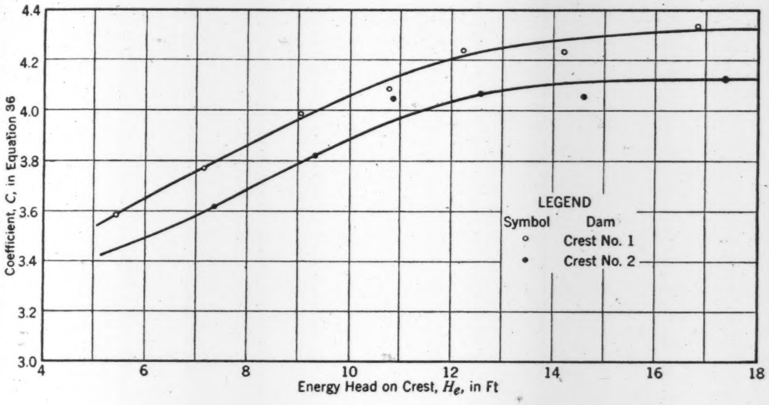

FIG. 84.—COEFFICIENTS FOR FREE DISCHARGE

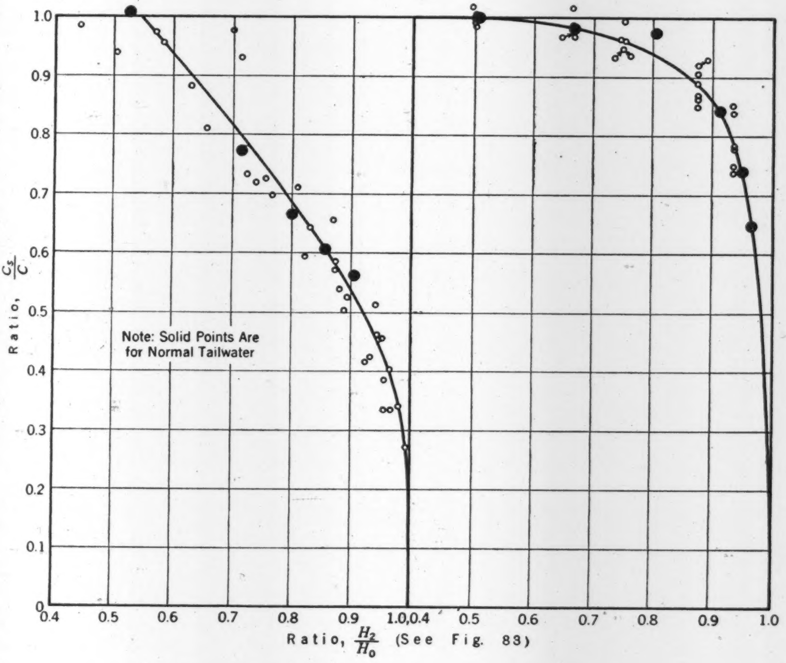

FIG. 85.—COEFFICIENTS FOR SUBMERGED DISCHARGE

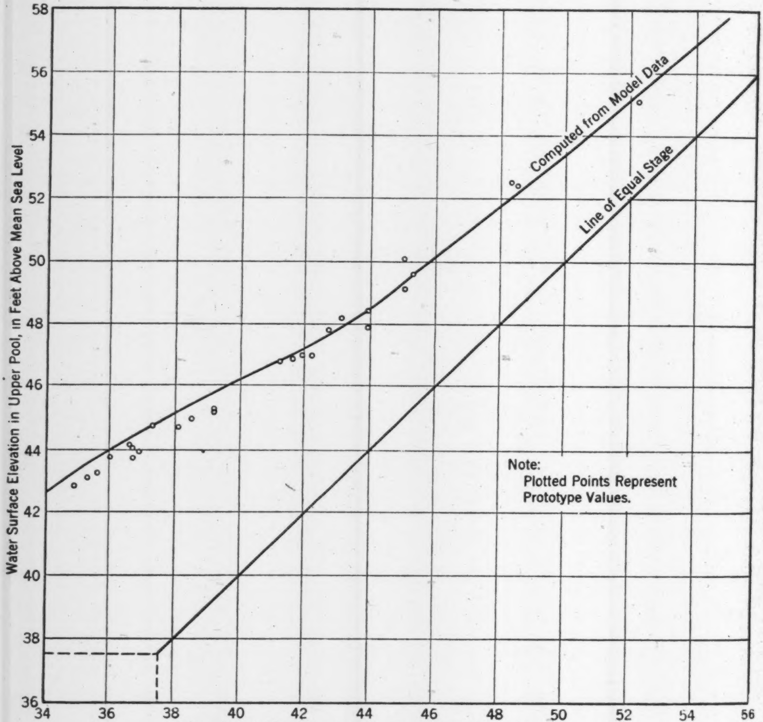
upper and lower pool gages. While the water supply was maintained at the same rate, another water level was simulated in the lower pool, and the gages were read again. This procedure was followed until a sufficient number of points had been obtained to describe the headwater-tailwater relation for the given discharge. Then, a different rate of flow was established and the tests were repeated. Seven discharge rates ranging from 25,000 to 165,000 cu ft per sec were simulated.



Note:
Plotted Points Represent
Prototype Values.

FIG. 86.—STAGE RELATION CURVES—MODEL AND PROTOTYPE

The headwater-tailwater relations observed on the models of crest No. 1 and crest No. 2 are shown in Fig. 83. The coefficient C in the formula (see Eq. 13),

$$Q_p = C\,L\,H^{1.5}_e \ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

computed for each discharge rate in the region of free flow is shown graphically with respect to total head in Fig. 84. Coefficients of discharge under submerged flow conditions were also computed by Eq. 13 (or Eq. 36) for each crest at several stages of submergence. Fig. 85 contains the ratios of coefficients for submerged to free flow in relation to the ratio of upstream to downstream water levels above the crest of the dam for crests No. 1 and No. 2, respectively. The tests indicate two marked distinctions in the characteristics of the respective crests. Crest No. 1 is shown in Fig. 84 to be more efficient in the region of free flow, whereas crest No. 2 is decidedly more efficient under submerged flow conditions. The change takes place at approximately $\frac{H_2}{H_0} = 0.50$, the point below which the submergence has no apparent effect on the coefficient ratio. These results verify conclusion (*a*) reached by Mr. Soucek: "The effect of submergence on the discharge is affected by the shape of the spillway * * *." However, contrary to Mr. Soucek's findings, the tests on crest No. 1 and crest No. 2 showed no consistent relation between the rate of discharge and the coefficient pattern.

Comparison of Model and Prototype.—After the prototype had been constructed, the water-surface elevations in the upper and lower pools were observed on staff gages at frequent intervals during the passage of several peak rates of discharge over the crest. From these readings, hydrographs were constructed from which the simultaneous elevations of the upper and lower pools were read at the peak of the hydrograph when the flow could be assumed to be approximately constant. The relation of the water levels observed during several freshets is shown in Fig. 86. In the same figure is shown this relation computed from the discharge coefficients determined in the model. The pool relation curves shown in Fig. 83(*a*) could not be compared directly with the data observed in the prototype because the prototype crest was constructed to a higher elevation than the model crest and, furthermore, because the tailwater rating curve existing in the prototype was different from that used in the model. This correlation between the model and prototype is considered to be very satisfactory and substantiates Mr. Soucek's conclusion (*d*)—"Reasonably good agreement may be expected between spillway models and prototypes of the sizes used in these tests under submerged as well as free flow conditions."

JACOB E. WARNOCK,[36] M. AM. SOC. C. E., AND H. G. DEWEY, JR.,[37] JUN. AM. SOC. C. E.—It is most gratifying to note the number of excellent discussions provoked by this Symposium. No doubt the wartime duties of many other interested engineers have prevented them from submitting a discussion or concrete evidences of model-prototype conformity. The excellent examples of conformity submitted by Messrs. McConaughy, Hall, and Blaisdell add much to the value of the Symposium.

Professor Streeter has stated that personnel of hydraulic laboratories are inclined to rely upon the model for the answer to all hydraulic questions instead of applying fundamental principles. It is true, of course, that in recent years hydraulic engineers have relied heavily upon hydraulic model studies to solve many unprecedented problems. Professor Streeter knows from his experience that many of these problems are not susceptible to fundamental analysis, and, even if an application of fundamental principles were possible, those responsible for the design of a structure would not be satisfied until a model test had been made. On the other hand, many hydraulic problems have been analyzed in laboratories by application of fundamental principles, resulting in a limited amount of testing or no testing at all. Eventually, hydraulic engineers should become more adept at preparing satisfactory designs of structures by using knowledge gained from previous model tests of similar structures and from checks on the prototype performance. As soon as the modern theories of fluid mechanics become more practical and are shown to be entirely adequate, the need for model tests will probably decrease and the general application of fundamental principles should be predominant. Professor Streeter believes that the application of fundamental principles will yield more reliable information at a smaller cost. This might be quite true, provided that the reliability can be established to the satisfaction of all concerned. Unfortunately, this is not generally the case, since some designs so analyzed have either yielded uneconomical solutions or inadequate designs as shown by subsequent model studies. An inspection of some of the older hydraulic structures in the United States also will show this to be true, since model studies were not used so extensively at the time of their design, but fundamental principles were relied upon almost entirely.

[36] Engr., Hydr. Testing Laboratory, U. S. Bureau of Reclamation, Denver, Colo.

[37] Capt., Corps of Engrs., U. S. Army, U. S. Waterways Experiment Station, Vicksburg, Miss.

Eq. 18, computed by Professor Streeter, is in good agreement with Curve 3, Fig. 13. It will be recalled that Curve 3 was obtained by treating the bellmouth entrance as an orifice, using the pressure drop as measured in the bellmouth of the prototype (Fig. 4). Either Eq. 18 or Curve 3 is more reliable than Curve 4, which was derived from prototype discharge measurements. Since these discharges were obtained by a rather indirect method, they were not used to compute the prototype friction factor.

In regard to neglecting the kinetic energy correction factor, Professor Streeter suggests that, in using $K_e = 1.00$ instead of 1.02, the prototype friction factors in Fig. 6 may be 25% too high. If, in 40 ft of conduit, the measured friction loss is assumed as 2.87 ft for a head of 150 ft, the friction factor would be 0.0073; if $K_e = 1.02$, the friction factor would be 0.00715, or 2% less than the former. Neglecting the kinetic energy correction factor would not change the measured friction loss, of course, but would make the computed friction factors too high (although only about 2% and not 25%). It was previously recognized that the velocity distribution in so short a conduit would not be sufficiently developed to allow a good determination of the friction factor. As Professor Streeter suggests, velocity distributions should have been obtained in the test section, but this was impossible since no provisions were made on the prototype for velocity measurements—another example of the difficulty of obtaining proper measurements and correlation.

In regard to the statement that the discrepancy between model and prototype pressures was partly due to unstable flow in the model, it was felt that viscous effects in the model were more predominant than in the prototype. That this may be true is demonstrated by Mr. Douma (see Fig. 80).

Professor Streeter's demonstration of estimating the prototype pressure drop from crown to invert from the model pressures is particularly interesting. Although the difference in pressure between the crown and invert is of interest, the actual pressures along the crown and invert are of more concern.

Messrs. Tower and Pafford request that hydraulic laboratories compile data from model experiments and prototype measurements in a form suitable for design purposes, thereby aiding designing engineers and reducing the number of model tests of nearly identical structures. This is a good request and should be given more attention. Unfortunately, those who control the functions of many hydraulic laboratories are primarily interested in the solution of immediate problems and, as yet, have allowed those in the laboratory but little time for compiling data or for conducting research which would eventually furnish design data. In regard to data on the curve of the lower nappe of the sharp-crested weir, the laboratory of the Bureau of Reclamation, in 1942, completed a comprehensive research program on the nappes of such weirs (77).

Mr. Pafford's suggestion of keeping piezometers open in the prototype by frequent flushing with clear water is recommended, but, as he suggests, it will be a nuisance to the operating personnel. It might be added that it would be more of a nuisance during construction when the danger of plugging is probably the greatest. The use of removable, flexible, corrosion-resisting wire would be excellent for short piezometer tubes, but for long tubing this method would probably be impracticable.

Mr. Gilardi wishes to lift the veil of secrecy surrounding some engineering mistakes, and cites as examples two cases where solutions by model studies were not followed, causing inadequate prototype designs. He seems to blame both the laboratory and project, or consulting engineers. Obviously, if the latter group has a poor working knowledge of model studies and little faith in the recommendations obtained from them, and wishes to adhere strictly to its own preconceived ideas, then unfortunate results may occur. On the other hand, there should be little excuse for well-trained and thoroughly experienced laboratory personnel arriving at erroneous conclusions, provided they receive full instructions relative to the prototype conditions from the project engineers. In this regard it is believed that better results can be obtained to the satisfaction of all concerned if the designing engineers are able to keep in close contact with the laboratory through frequent visits.

Mr. Douma's discussion of similitude is quite appropriate. It is agreed that better results could have been obtained had the model of the outlets been built to a larger scale—the surfaces, however, were about as smooth as could be obtained. Had the tests been run at higher heads, disregarding the scale ratio, it is believed that the pressure analysis would have been more consistent using the dimensionless parameters shown in Figs. 7, 8, 10, and 11. The use of outlet models of sufficient size to obtain a larger Reynolds number so as to be somewhat closer to the prototype values of friction factors would have been impossible because the discharge facilities of the laboratory would have been exceeded. On problems where the prototype Reynolds numbers are not too large, it may be easy to close the gap between model and prototype; generally, however, the value of the Reynolds number in the model would have to be increased considerably to reach the point where the variation between the friction factor and the Reynolds number is negligible and at the same time of the same order of magnitude as the prototype friction factor for the entire range of discharges to be studied.

MARTIN E. NELSON,[38] M. AM. SOC. C. E., AND JAMES J. HARTIGAN,[39] ESQ. —An interesting analysis of the relative effectiveness on lock efficiency of area changes in culverts and ports has been developed by Mr. Kreiss. From Eq. 33, he has derived an expression for the area ratio which satisfies the condition of equal percentage changes in port area and culvert area being equally effective in changing the discharge capacity. When μ is 0.15, this area ratio of 1.45 is numerically about the same as the area ratio for square-cornered ports used in early lock designs.

Also, it can be shown from Eq. 33 that the upper limit of the area ratio, at which percentage increase in port area affects the discharge capacity, is

$$x = \frac{1}{\mu \log_e{}^{10}} \dots\dots\dots\dots\dots\dots (37)$$

This limiting area ratio is 2.89 when μ equals 0.15.

For the venturi-shaped ports of the first[6c] and third[6d] models, it is obvious from Figs. 25(*a*) and 34(*a*) that the upper limit for effective increase in area ratio has not been reached in either model test. Area ratios for these two models are 2.22 and 1.65, respectively. Similarly, in the third lock[6d] prototype, having an area ratio of 2.19, all lock-chamber ports are used effectively. However, in the first lock[6c] prototype the distribution of flow curve of Fig. 25(*a*) shows an effective use of only 17 of the 20 ports, corresponding to an area ratio of 1.9. The μ-value satisfying Eq. 37 is 0.23 when the area ratio is 1.9. It would be desirable to have series of tests on venturi-shaped ports, having different divergence angles, to determine whether μ in Eq. 31 remains constant.

Tests have been made on a lock model equipped with ports similar at the culvert end to the bellmouth entrance of the lock-chamber ports of the third lock[6d] (Fig. 24), but having parallel instead of divergent walls. This type of port has a larger discharge capacity than the venturi-shaped port for corresponding area ratios. The tests showed that increase in area ratio above 1.8 did not change the discharge capacity of the lock, area ratios of 1.0, 1.4, 1.8, 2.2, and 2.8 having been tested.

The authors are very grateful to Mr. Webster for his description of the testing apparatus used in obtaining performance data in the prototype locks. This apparatus was developed after a considerable investigation of commercial hydraulic testing equipment failed to bring to light any instruments suitably adaptable to the tests in view. The equipment proved to be remarkably well suited to the severe conditions under which it was necessary to operate.

The coordination and timing of tests performed simultaneously and at great distances on the lock chambers were facilitated greatly by using two sets of sending-receiving short-wave radios to transmit signals from the central operating station to the observation stations. For instance, in making simultaneous lock-stage tests at the two ends of a lock, time signals, originated by an automatic electric timer, were picked up on the radio receiving sets at the observation stations, indicating to the observers when to record the stage on the manometer charts. Likewise, the observers could be kept informed of the start, end, and intermediate progress of the valve operation, and other pertinent information could be transmitted readily from one station to another.

[6c] Pickwick Lock.

[6d] Guntersville Lock.

J. C. Stevens,[40] **M. Am. Soc. C. E., and R. B. Cochrane,**[41] **Assoc. M. Am. Soc. C. E.**—From the standpoint of design of the crest profile, Mr. Grimm's discussion of the writers' paper was enlightening. The writers realized that operation of the dam with the gates in the upstream slots would be abnormal and that such gate operation was for emergency purposes only. Since such operation data were procured with the model, a splendid opportunity to obtain corresponding prototype data was presented. The fact that the prototype pressures obtained with the gate in the upstream slot did not corroborate the model pressures constitutes certain "negative" information which at times is just as valuable as "positive" information. The writers agree most heartily with Mr. Grimm in his statement that "A model study of spillway crests under controlled atmospheric pressure would be timely and of decided value as a research project to supplement present knowledge."

Edward Soucek,[42] **Assoc. M. Am. Soc. C. E.**—The interest shown in the paper is most gratifying; particular thanks are due to those who have presented previously unpublished data.

Professor Johnson's remarks deal primarily with unsubmerged spillways, but the tests of the Upper Narrows Dam are of much interest. It is regretted that the model details were not illustrated or described. Since the prototype is curved in plan, similarity demands convergent flow over the spillway and radial approach velocity; these conditions are difficult to obtain on a sectional model in a flume only 6 in. wide. End effects sometimes are feared in so narrow a flume, even when a straight spillway section is represented. The agreement between discharge curves of the 1 : 25 and 1 : 40 models seems reassuring in this connection; certainly the agreement tends to confirm the principle that a spillway model need not exceed a reasonable size. The small effect of surface roughness upon the discharge of the two larger models is highly significant. The curve for the 1 : 100 model shows that it is too small for rating the prototype; it may be too small also for accurate determination of the nappe profile. In connection with that phase of the work especially, but also for the discharge measurements, supplementary measurements were undoubtedly necessary to determine that a 1-in. pipe provided complete aeration of the nappe. The writer has used a small U-tube, partly filled with water and connected to the space beneath the nappe, to indicate the subatmospheric and fluctuating pressures that accompany incomplete aeration. This check is recommended strongly as surprisingly large vents have been required in some cases.

[40] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

[41] Capt., Corps of Engrs., U. S. Army, Res. Engr., U. S. Engrs., Bonneville, Ore.

[42] Senior Civ. Engr., U. S. Engr. Office, Wilmington, N. C.

It is doubtful that a "more definite measure of the agreement between the various studies" is gained by use of the exponential equations derived by Professor Johnson. For that purpose, the curves of Fig. 64 leave nothing to be desired. It appears that use of the conventional exponent with a varying coefficient is more convenient for nearly all purposes, cases in which the discharge equation must be integrated being an important exception.

Professor Johnson's statement that "model studies made of existing structures are more likely to be academic in character" is a well-meant generalization; it is questioned only because it is not entirely harmless. In the writer's experience, exceptions have been so frequent that they cannot be said to prove the rule. A few cases will be mentioned: (1) A large spillway was tested to determine a rating which was not otherwise obtainable and for study of the effect of proposed modifications; (2) a large waterway was studied to verify the ability of the model to reproduce wave phenomena previously observed on the prototype—then the model was used not only for the study of proposed modifications but also for investigation of extreme conditions which it was unsafe to create and impracticable to observe on the prototype; and (3) a lock was tested to verify the subsequent use of models for study of proposed structures and for the development of apparatus and technique—an inexpensive, practical, and important modification, which probably will be applied to the existing structure, was discovered as an incidental by-product. It is true that models of existing structures frequently are tested in college laboratories. Such tests may indicate a feasible modification for improved performance or may shed light on a poorly-understood phenomenon which has been observed on the prototype. A useful by-product of the tests described in the paper was their immediate local application for stream gaging under flood conditions. Possibilities for valuable model-prototype comparisons are almost unlimited. A student can make a far worse choice in research problems than a study of an existing structure. Believing that such studies should be encouraged, the writer hopes and believes that their character will be judged by the care with which the subject is selected, the manner in which the experimental work is performed, and the skill with which the test results are interpreted.

Professor Cox points out that a sharp-crested weir is affected by the tailwater elevation when submergence, as defined by the writer, does not exist. The point is well taken; nevertheless, the writer prefers the original definition to the one proposed on the basis that the name of a phenomenon should be descriptive rather than indicative of its effects. The more general term "affected by tailwater" would cover the situation.

The writer does not advocate any significant departure from geometric similarity; accordingly, he agrees with many of the statements by Professor Cox regarding the flow downstream from a submerged dam. He still believes, however, that the tailwater should be measured beyond the effects of the dam whenever possible and that this is possible in most cases. The channels downstream from low dams can be represented reasonably well by a flume, when necessary, by molding the channel bottom to represent the variation in depth with distance from the dam. Only if such representation is impossible would the writer adopt the expedient of measuring the tailwater within the effects of the dam. In such a case, the problem of relating the observation to the backwater curve downstream from the dam remains unless discharge measurement is the only objective. The error possible in making this estimate is believed at least to equal the effect of a reasonable approximation to the channel cross section in the model. The several advantages of measuring the tailwater beyond the effects of the dam were stated in the paper and need not be reiterated.

Fig. 68 exhibits a tendency similar to that revealed by Fig. 54—the greatest submergence at which the plunging nappe condition can be maintained decreases as the head increases. Professor Cox' correction curve for adjusting the observed submergence would be expected to exhibit a loop or other discontinuity corresponding to the changes in behavior of the nappe. By the use of this curve and the equations which he derived, Professor Cox obtained computed discharges in good agreement with the observations. In at least one other case (50) Professor Cox has used his method with good results. The writer does not know the scope and limitations of the method. Dimensionally, it appears subject to question but it has been used very successfully by Professor Cox.

In stating that no gagings were made when the ice jam was within 500 ft of the dam, the writer was trying to show only that the jam had no effect except the raising of the tailwater to a level somewhat higher than would occur normally at the same range of discharge. It is regretted that this statement led Professor Cox to speculate upon the existence of a reverse bottom current. It is believed that such a current would have been detected from the angle assumed by the cable which supported the meter and the weights. During all except one of the measurements, the distance to the ice jam was much greater. Angularity of subsurface velocities and turbulence may have affected the measurements, producing results similar to those suggested by Professor Cox.

The data presented by Mr. Walton, as he states, are surprising in their close agreement to the U. S. Deep Waterways tests. Probable reasons for this correspondence are considered subsequently. On the basis of Mr. Walton's observations, the writer agrees that the behavior of the nappe requires consideration in some cases. It might be inferred that this effect is present or perceptible only when the spillway is particularly "sensitive" to submergence. The writer's opinions concerning the measurement of heads coincide with those of Mr. Walton; certainly the tailwater may be measured within the region affected by nappe conditions when no alternative exists.

Mr. Tower expresses the now general acceptance of the nappe-shaped profile. It is interesting to point out, however, that the shape of the dam tested was established by an eminent hydraulic engineer, not "by reason of the lack of adequate information" but in order to modify an existing structure most economically, so as to accommodate a large tunnel for steam pipes and other utilities. The dam always is submerged when a major flood is in progress. The writer knows of no evidence that the spillway is not as efficient as a conventional nappe-shaped profile when the submergence is high; there is no deterioration that could be attributed to the shape of the spillway. This exception to a perfectly valid general rule illustrates the need for complete data before passing judgment on a design.

Professor Mavis presents a useful formula and valuable data. His qualified acceptance of the writer's statements regarding the effect of nappe conditions upon discharge is especially pertinent in view of Mr. Walton's observations. The equation presented is equally applicable to both sections shown in Fig. 73. Since the effect of submergence doubles for each 5% increment in the submergence, the relationship is remembered easily. For a rounded cross section which supports the nappe, the equation is certainly more correct than the widely-quoted and much-used curve based on the U. S. Deep Waterways tests. Further evidence to this effect appears in another discussion which is considered later.

Professor Mavis' conclusion (b) that "the generalized relationship between submergence percentage, *p*, and the ratio of submerged to free discharge, * * * is valid within the scatter of field observations on the prototype" is accepted but the qualification should not be ignored. For preliminary designs or for estimates of the effect of submergence upon the discharge over well-rounded crests when model data are not available, the equation may be used to good advantage. For analysis of test data and their application to geometrically similar prototypes, retention of the discharge as an independent variable is believed to justify fully the minor complications necessitated.

Mr. Nelson kindly has devoted a large part of his discussion to the writer's paper. This presentation of new data leaves little opportunity for comment in addition to a statement of approval. Attention is called to the better collocation of those observation points which represent normal tailwater in Fig. 85. These data support the contention that discharge should be treated as an independent variable. The agreement of the "effect of submergence curve" for the well-rounded crest with the equation suggested by Professor Mavis confirms the applicability of the relationship.

Mr. Nelson measured the water levels beyond the immediate effects of the dam as the writer recommends. The agreement between model data and prototype observation is highly satisfactory, particularly in view of the minor departures from complete similarity. In one respect, these tests were contrary to the writer's findings; the tests did not reveal a consistent relationship between the discharge and the effect of submergence. In this connection, the comments accompanying Figs. 52 and 53 should be emphasized. The tendency for the effect of submergence to increase with the discharge is clearly evident but the consistency of the data is exaggerated to some extent. When the curves were sketched originally, all differed in shape; some actually intersected. By a process of repeated adjustment, all of the curves except the one for the lowest discharge were drawn to conform to an average pattern. It seems possible that a similar smoothing process would reveal a consistent tendency if applied to the data of Mr. Nelson. Fig. 83 shows an excellent method of representing submerged spillway data graphically.

The last paragraph of Mr. Blaisdell's discussion deals with the writer's use of the discharge as an independent variable; he recommends that this variable be ignored in determining the effect of submergence. The writer emphatically disagrees with the suggestion and the implied ideas.

At a submergence of 85%, the reduction in discharge produced by submergence may be as little as 7%. The 3% error which Mr. Blaisdell considers tolerable thus amounts to more than 40% of the effect being investigated. For high submergences, the absolute error in discharge can be at least as great as 10%, and much greater if the average curve is based on a small range of discharge. It is true that for submergence exceeding 85% "the submergence curves are steep, and small errors in determining the submergence result in large errors in the submerged discharge correction." However, water levels are observed so easily and accurately that there is no reason whatever for any significant error in the determination of submergence. An average submergence curve is also steep. The remote possibility of a small error in the submergence by no means justifies the deliberate introduction of a large error, particularly when the only possible gain is the avoidance of a simple computation requiring at most a few minutes' time.

The data were presented in a manner intended to expedite comparison with published material. It was stated that a direct method of making the calculation could be derived easily if a large number of calculations were necessary. The data were so arranged that no trial computations were required in order to check the results. The measurements on the model were intended for comparison with prototype measurements; an average difference of a few per cent, probably caused by errors inherent in the method of gaging the prototype, was anticipated and realized. The possibility exists that, in the future, the model measurements will be compared with more accurate prototype observations. Under these conditions, use of Mr. Blaisdell's method would have been improper. If (as Mr. Blaisdell states) the result of a refinement which avoids an error of 10% or more is a fictitious accuracy, literature records many unwarranted model studies.

In the application of submerged spillway data to a particular problem, the user is best qualified to judge the magnitude of tolerable errors. For estimating a flood-crest elevation, precision might be quite unnecessary; in designing a submerged sill to regulate the Great Lakes, accuracy of the highest order might be essential. It is believed that the experimenter is under obligation to present data with meticulous precision, if possible in a form which enables the designer to make such short cuts as the specific application may justify. A statement to the effect that most uses do not justify great precision is true but hardly necessary—this fact is well known and universally accepted. Objection to an accurate analysis which permits the designer to make an application consistent with his purpose, and without disadvantage, is not considered indicative of a "practical standpoint."

A careful distinction should be made between a legitimate simplification and a rough approximation adopted only to avoid computation. A simplification is proper when the materials dealt with have physical properties which are so complex or variable that an involved equation is unwarranted for physical reasons and undesirable because it obscures significant relationships. Mr. Blaisdell's suggestion is not based on physical reasons; nor does it result in a simplification warranted by the loss of accuracy involved. Its proposal can be based only upon an unwarranted mistrust of the reliability of hydraulic models or of the accuracy obtainable in the design of hydraulic structures.

A number of the discussers have commented favorably upon various indications of accuracy in the experimental work. The writer wishes to emphasize, as stated in "Acknowledgment," that the model tests were conducted by Mr. Morgan.

There were no comments on the writer's statement that the discrepancy between model and prototype is probably chargeable to the latter. Five years have passed since, in 1938, this statement was made in the original draft of the paper. The writer's present belief is that the discharge indicated by a well-designed spillway model, when the model head exceeds 3 in. or 4 in., is fully as accurate as that obtainable by any field method in current use.

The data presented in the discussions fully confirm the conclusion that the effect of submergence upon the discharge is a function of spillway shape. This fact has not always been as evident as it now appears; once the writer was advised to check some submerged spillway data very carefully because they did not agree with the U. S. Deep Waterways curve. This suggestion was influenced by the agreement between Mr. Walton's data and the U. S. Deep Waterways tests. Although Mr. Walton's spillway and the U. S. Deep Waterways spillway differ in shape, they have a common characteristic. This is the factor believed to control the effect of submergence upon the discharge—namely, the distribution of pressure within the nappe at or near the spillway crest. Since the nappe springs free of these spillways or tends to do so, the occurrence of subatmospheric pressure beneath and within the nappe affects the head-discharge relationship. Submergence of these spillways tends to modify pressure conditions radically at the crest, making them "submergence sensitive." When the nappe is in contact with the spillway at all points with atmospheric pressure at the water-masonry interface, or particularly when the nappe exerts a pressure against the spillway, submergence has a smaller effect upon the pressure distribution at the crest. For this reason, a dam with a stable nappe is less affected by submergence. This is the case on the spillways tested by Professor Cox, Professor Mavis, Mr. Nelson, and the writer. The difference in the submergence effect in the two crests tested by Messrs. Nelson and Hartigan confirms this idea. A comparison of the several spillway sections reported indicates that this explanation is reasonable. (It should be observed that the vertical face of the U. S. Deep Waterways section is on its downstream side.)

If (as the writer believes) the data brought to light in the discussions is indicative of the wealth of information available from the personal files of engineers, the mere announcement, for discussion, of subjects carefully chosen by the appropriate committees may be a more effective method of developing references upon suitable problems than waiting—sometimes many years—for an author to introduce a subject concerning which information is needed badly. In the present case, the prevailing method of computing the effect of submergence upon the discharge actually produced errors, when applied to modern spillways, greater than the effect of completely ignoring the submergence.

That this observation can now be made as an established fact rather than as an isolated opinion is due to the efforts of those who presented discussions. The writer is pleased in having had a small part in correcting this situation and in making more reliable quantitative data generally available.

FREDERICK R. BROWN,[43] JUN. AM. SOC. C. E.—Most of the papers and discussions on model-prototype conformity have dealt with hydraulic structures and tests on models constructed geometrically similar to their prototype counterparts. There are other types of model studies, however, which were given little emphasis in the Symposium. This is probably due to the fact that few engineers have tried to study the model-prototype conformity that exists for geometrically distorted models constructed for the solution of problems on channel capacity and bed movement.

Models of hydraulic structures practically always are constructed to the same horizontal and vertical scales, and dynamic similitude is attained in so far as possible by operating these models in accordance with the Froudian scale relationships. In most cases a large model scale must be used to satisfy the roughness ratio requirement which can be shown to be equal to $(L_r)^{1/6}$; thus, as the model scale decreases, the smoothness of the model must be increased. Geometric similitude must be maintained because it is important to the success of the study that the magnitude and direction of prototype forces and flow paths be reproduced accurately.

In the case of some river models, however, where the area to be reproduced is large and it is necessary that the vertical scale be larger than the horizontal scale to obtain measurable quantities on the model or where it is necessary to add an additional slope distortion for movement of bed material, neither geometric similitude nor correct dynamic similitude is obtained. Complete similitude is not essential if care is taken in selecting the model scales for solution of the problem at hand. If the problem is one involving channel capacities or study of flood-crest profiles, the model scales can be distorted considerably inasmuch as there is no need for the exact reproduction of velocity distribution, paths of flow, etc. All that is necessary to insure reliable model results in the foregoing case is to adjust the model roughness in order that a discharge and velocity scale will be obtained that will permit the reproduction of the desired stage-discharge relations and the average change in potential and kinetic energy at varying cross sections. If the problem involves the movement of bed material, the distortion of model scales must not be too large. The success of this type of model depends upon the reproduction of the proper velocity distribution for movement of the bed material. If the horizontal and vertical scales selected are such that the distortion is low and the stream is wide with respect to the depth, the distortion will not alter the general shape of the channel, and close similarity of velocity distribution will exist.

In the case of the Mississippi River channel model described in the Symposium, the horizontal scale was 1 : 600 and the vertical scale was 1 : 150

---

[43] Associate Engr., U. S. Waterways Experiment Station, Vicksburg, Miss.

which gives a distortion of 4. This distortion was small enough so that the velocity distribution and current directions were reproduced accurately. No tests of improvement plans were undertaken, however, until the accuracy of the model was insured. The accuracy of the model was established by a verification procedure in which model operating conditions were developed such that the movement of bed material in the model was consistent with that in the prototype. In order to provide adequate movement of the coal bed material, it was found necessary to provide a slight additional slope distortion. Instead of altering the slope, either the discharge scales or the time scales or both could have been adjusted to reproduce the prototype bed movement—that is, the discharge scale or the length of run at low stages could be increased over that used for high stages.

Mr. Einstein states that, during a visit to the U. S. Waterways Experiment Station at Vicksburg, he was astonished to see how much the natural roughness of a model must be increased to counteract the effect of the distortion on friction. This raised the question in his mind of the reliability of distorted hydraulic models.

The actual roughness used in distorted channel models at the Experiment Station is placed in accordance with accepted model practice and can be shown to be mathematically correct. If the linear scale and the distortion is small, however, it may become impossible to make the model smooth enough. On the other hand, if the distortion is too large, the model cannot be made rough enough. Between the two aforementioned extremes, there are model scales that will permit the use of the theoretical roughness ratio [$n_r = (R_r)^{2/3} (L_r)^{-1/2}$], in which R_r is ratio of the hydraulic radii for the model (R_m) to the prototype (R_p). It is not necessary, however, to use the theoretical roughness values inasmuch as a number of discharge scales with their corresponding roughness values will provide identical flow lines.

FIG. 87

An excellent example to demonstrate that it is possible to have various combinations of roughness and discharge scales for the reproduction of identical flow lines was computed by Lieutenant Tiffany (78). It was shown that, with a model constructed to a horizontal scale ratio of 1 : 200 and a vertical scale ratio of 1 : 80, the following relationships would obtain for the channel whose cross section is shown in Fig. 87: $R_r = \frac{R_m}{R_p} = \frac{0.245}{23.9} = \frac{1}{97.5}$; and

$$Q_r = (L\,y\,V)_r = \left(\frac{R^{2/3}\,L^{1/2}\,y^{3/2}}{n}\right)_r = \frac{1}{n_r} \times \left(\frac{1}{97.5}\right)^{2/3} \times \left(\frac{1}{200}\right)^{1/2} \times \left(\frac{1}{80}\right)^{3/2} = \frac{1}{n_r} \times \frac{1}{215{,}000}.$$

Thus, from the foregoing computations it can be seen that the discharge and roughness ratios are dependent upon each other. Assuming the prototype roughness to be about 0.024, the following conditions would obtain:

Q_r	n_r	n_m
1 : 120,000	1 : 1.79	0.0134
1 : 128,000	1 : 1.68	0.0143
1 : 143,000	1 : 1.50	0.0160
1 : 150,000	1 : 1.43	0.0168

In this case the theoretical discharge scale of 1 : 143,000 [$Q_r = L_r\,(y_r)^{3/2}$] could have been used in the model since a model roughness of 0.0160 is possible of attainment. However, in the event that the model roughness indicated by the theoretical relationship was too rough, the model could have been roughened as much as practical and the discharge scale changed accordingly to reproduce the prototype flow lines.

For further detailed information regarding the accuracy of distorted models and the verification procedure, for movable bed models, reference is made to the Society's Manual on "Hydraulic Models" (78*a*). It is recommended that any one connected with model investigations familiarize himself with this excellent dissertation on both distorted and undistorted models.

All in all, the distorted model provides a valuable tool for the solution of difficult problems. If the tool is handled correctly, a quantitative interpretation of the results pertaining to the problem for which the model was designed is possible. The departure from conditions of similitude, however, makes it necessary to qualify other results or information. Experienced model technicians realize the true value of distorted models and can be depended upon to interpret the model results correctly.

Comparable model and prototype data are difficult to obtain for channel models inasmuch as the structures or plans developed through model investigation often are not installed or have not had time since construction to indicate changes caused by their installation. Of the amount of information available, however, the prototype performance is bearing out the predictions of the distorted scale models, in practically every case.

SEISMIC SUBSURFACE EXPLORATION ON THE ST. LAWRENCE RIVER PROJECT

BY E. R. SHEPARD,[1] ESQ., AND REUBEN M. HAINES,[2]
ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. R. WOODWARD MOORE, ARTHUR J. GRIER, F. W. LEE, L. DON LEET, WILLIAM L. SHANNON AND WINTHROP A. WELLS, AND E. R. SHEPARD AND REUBEN M. HAINES.

SYNOPSIS

The seismic method of subsurface exploration was used extensively by the Corps of Engineers, U. S. Army, in preliminary studies of the St. Lawrence River Project in the International Rapids Section. A well-defined interface between the glaciated rock and the overlying till made possible the determination of the depth of overburden with satisfactory accuracy. Considerable success was also attained in determining changes in the overburden. The program included tests in both quiet and swift water, for which special apparatus and methods were devised. The use of the seismic data enabled the design of concrete structures, navigation channels, and hydraulic cuts to proceed more rapidly than if exploration consisted only of drill holes. By correlation with drill hole data and the general geology of the region, the results aided in determining the extent and depth of various deposits of glacial till and other types of overburden and also their condition of density and compaction. The subaqueous tests are believed to be unique for obtaining information of the type required for this project. As the results of the subaqueous exploration were satisfactory for this project, the use of the seismic method should be broadened in future investigations to include similar conditions.

INTRODUCTION

Late in 1940 a program of subsurface investigations was inaugurated to obtain data for the design of structures for the St. Lawrence River Project by the Corps of Engineers, U. S. Army, with a district office at Massena, N. Y.

NOTE.—Published in December, 1942, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Senior Physicist, Corps of Engrs., U. S. Army, Washington, D. C.

[2] Engr., Corps of Engrs., U. S. Army, Massena, N. Y.

The project, extending a distance of approximately 45 miles, is located in what is known as the International Rapids Section of the St. Lawrence River. Because of the large number of concrete structures, dikes, navigation channels, and hydraulic cuts, the problem of making adequate subsurface explorations assumed major proportions. Prior to 1940, sufficient studies and investigations had been made by the United States and Canadian governments, and various private companies, to determine the general plan of the project and the approximate location of each element. The data, however, were far short of those which would be required for determining the most feasible and economical locations and designs for the various elements and for making cost estimates.

At the outset of the present exploratory program it was recognized that subsurface conditions were favorable to the seismic method of exploration, that the interface between the hard rock and the overburden could be determined with fair accuracy by that method, and that some success might be achieved in determining changes in the overburden. From the previous subsurface and geological surveys, it was known that the bedrock in the region is of sedimentary origin, consisting mainly of dolomite and limestone. Glacial action had removed the residual soft, weathered rock, leaving a generally smooth, undulating, hard rock surface of low relief, broken by occasional valleys, ridges, and faults. The overburden consists of deposits of variable glacial till which appears in the form of elongated ridges at the surface and deposits of clays, silts, and uniform sands in the valleys between the till ridges.

The purpose of the seismic program was twofold: (1) To guide the drilling program and thereby limit it to obtaining necessary and essential data; and (2) to augment the drilling program with a large number of less expensive tests in areas where the required information could be obtained by that method. Extensive tests were made at sites where very little prior information was available, particularly in the numerous areas where cuts, channels, and canals were projected. Tests were also made to obtain data between drill holes. Considerable work was done in the river channel as well as on land. At the Long Sault Dam site, seismic tests were made in very swift water where drilling would have been exceptionally expensive and hazardous.

Except during March and April, when the ground was frozen, the explorations were conducted almost continuously from November, 1940, to October, 1941. During this time 408 lines were explored on land, 38 in quiet water, and 11 single-shot determinations were made in very swift water. Of this number 300 lines were explored to obtain information for the layout and estimates of canals, cuts, and channels. The seismic field party consisted of an instrument operator, one authorized dynamite man, and six helpers. The field crew completed from 2 to 6 lines per day according to weather conditions and the accessibility of the locations. Film records were developed daily by a local commercial photographer.

THEORY AND APPLICATION OF SEISMIC METHOD OF EXPLORATION

Principles Involved.—A comprehensive discussion of the principles involved in seismic exploration will not be given, as this subject is treated adequately in a voluminous literature on the subject. A brief description of the theory is necessary, however, if the significance of the data presented herein is to be understood.

The seismic method of exploration is based on the fact that the velocity of wave propagation in the earth's crust differs greatly in different substances. Granular and plastic materials, such as sand, clay, and gravel, transmit wave disturbances at velocities of roughly 800 to 8,000 ft per sec, whereas rigid rock transmits such disturbances at 10,000 to 20,000 ft per sec. This wide range in velocities in different kinds of soils and rocks is largely dependent on their elastic properties, a factor closely related to rigidity and hardness. To what extent other physical properties, as moisture content, texture, compaction, void space, cementation, and homogeneity, may be determined from velocity measurements is not fully known, although they do enter into the problem.

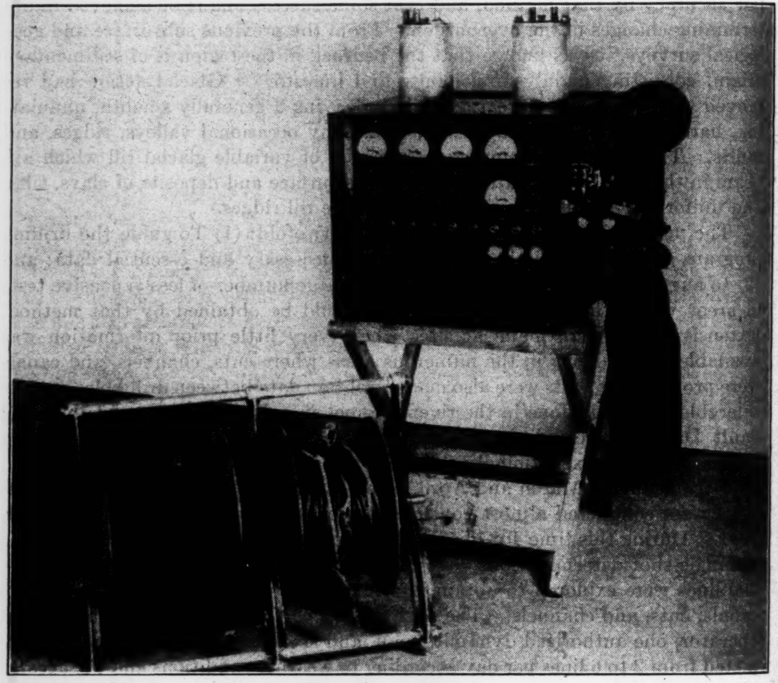

FIG. 1.—PORTABLE SEISMOGRAPH

Apparatus.—The seismic apparatus used for subsurface exploration on engineering projects consists essentially of one or more detectors or geophones and an oscillograph recorder. The detectors are connected electrically with the oscillograph so that the time of arrival of a wave disturbance at each detector may be recorded photographically. The disturbance is created by exploding a charge of dynamite in the ground at a known distance from the detectors. An electrical connection between the oscillograph and the detonating circuit records the shot instant. A time scale, made by an electrically driven tuning fork, is recorded on the oscillograph film. The seismic apparatus used in this investigation, shown in Fig. 1, was of a simple, portable type developed by the Public Roads Administration.

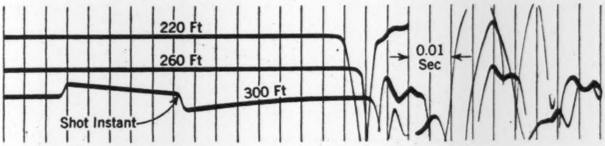

Fig. 2.—Typical Three-Channel Seismic Record

Application of Method.—With the type of apparatus used on the St. Lawrence River Project the usual field procedure is to place three detectors on the ground in a line, at intervals of 40 ft. Dynamite charges varying from 0.25 to 2.5 lb are buried to a depth of 3 ft and fired successively and at increasing distances along the detector line, beginning at 10 ft from the center detector and extending the shooting distance by intervals of about 50 ft to such lengths as may be required. A maximum shooting distance of three to four times the depth to which information is desired is usually necessary. Where possible the seismic lines are laid out along a surface contour in an effort to stay on one type and a nearly uniform depth of overburden. Although these conditions are not required for interpretation of the data, more accurate interpretations can be made if they exist.

From the film records, a sample of which is shown in Fig. 2, the time of the first arrival of wave travel from each shot to each of the three detectors is read and the results plotted in the form of a time-distance graph. In a homogeneous material the time-distance relation will be a straight line through the origin. This is evident from the fact that in such a medium the velocity of wave propagation is constant, or the time of travel is proportional to the shooting distance. It is also evident that the reciprocal of the slope of such a graph is a measure of the velocity in the medium.

When a layer of homogeneous soil is underlain by one through which waves travel at a higher velocity, such as that designated as clay in Fig. 3, there will be a critical distance, OF, for which the time of travel through the upper medium is just equal to the time of travel over the longer path which penetrates the lower medium. At this critical distance there will be a break in the time-distance graph to a different slope, CD, which represents the velocity of wave propagation in the second medium. In like manner, when the critical shooting distance, OG, is passed, the first arrivals will be through the high-velocity rock and the time-distance graph will assume the new trend, DW, the slope of which determines the velocity in the rock stratum. From the ordinates OA and AB on the time axis and the velocities indicated by the slopes of the several elements of the graph, it is possible to calculate the thickness of each stratum of overburden.

FIG. 3.—TIME-DISTANCE GRAPH FROM WHICH OVERBURDEN DEPTHS ARE DETERMINED

Determination of Overburden Depth by Two-Way Shooting.—In determining the thickness of overburden by the seismic method used on this project, it was necessary to measure the velocities of wave propagation in the several strata of which the overburden is composed. Because of sloping interfaces between different strata and also velocity irregularities in the upper soil, only apparent velocities are obtained from shots along one end of the seismic line. To obtain true velocities, therefore, it was necessary to shoot against the detector setup from opposite directions. The true velocities in the deeper strata were then found by taking the harmonic mean of the respective apparent velocities. When shooting "up-dip" along a sloping interface the apparent velocity in the deeper medium is higher than the true velocity, and when shooting "down-dip" the apparent velocity is less than the true velocity. Variations in moisture content, compaction, and other physical properties of the soil immediately beneath the detectors give rise to similar effects which might easily be interpreted as indicating a sloping interface. Where erratic and divergent data are obtained as a result of such conditions, it is only by a careful analysis of all data pertaining to a given area that errors of interpretation can be avoided. Considerable experience, good judgment, a knowledge of overburden conditions as they exist in the field, and a thorough understanding of the principles involved are required if satisfactory results are to be obtained by the seismic method of exploration.

After the velocities have been determined the actual computations of the depths of the several strata are relatively simple. The formulas by which depths are computed are given by Maurice Ewing, A. P. Crary, and H. M. Rutherford.[3] These formulas in the forms most frequently used are as follows:

$$H_1 = \frac{T_1 V_1}{2 \cos \alpha} \qquad \text{(1a)}$$

$$H_2 = \frac{T_2 V_2}{2 \cos \beta_2} - \frac{H_1 V_2 \cos \beta_1}{V_1 \cos \beta_2} \qquad \text{(1b)}$$

and

$$H_3 = \frac{T_3 V_3}{2 \cos \gamma_3} - \frac{H_1 V_3 \cos \gamma_1}{V_1 \cos \gamma_3} - \frac{H_2 V_3 \cos \gamma_2}{V_2 \cos \gamma_3} \qquad \text{(1c)}$$

in which (see Fig. 3): H_1, H_2, and H_3 = thicknesses of various layers; V_1, V_2, and V_3 = wave velocities in corresponding layers; T_1, T_2, and T_3 = the time intercepts on the Y-axis, OA, OB, etc.; α, β, and γ = angles of refraction; $\sin \alpha = \frac{V_1}{V_2}$, $\sin \beta_1 = \frac{V_1}{V_3}$, $\sin \beta_2 = \frac{V_2}{V_3}$, $\sin \gamma_1 = \frac{V_1}{V_4}$, $\sin \gamma_2 = \frac{V_2}{V_4}$, and $\sin \gamma_3 = \frac{V_3}{V_4}$.

In some instances, particularly for two or three layer formations, it is possible to use a simpler form of computation which gives values closely approximating those derived by the standard method.[4] In Fig. 3 the shorter formulas become:

$$H_1 = \frac{\overline{\mathrm{OA}} \times V_1}{2 \cos \alpha} \qquad \text{(2a)}$$

$$H_2 = \frac{\overline{\mathrm{AB}} \times V_2}{2 \cos \beta_2} \qquad \text{(2b)}$$

Results of Explorations on Land

Typical Time-Distance Graph.—The exploration program on the St. Lawrence River Project included seismic determinations in the river channels as well as on land. The work on land was done in accordance with the aforementioned methods of field procedure and analysis of data. A typical time-distance graph, derived from data obtained on the right abutment of the Long Sault Dam site, is shown in Fig. 4 and illustrates the method of plotting the data. With three detectors spaced at 40-ft intervals along the shot line, three points on the graph were obtained from each shot, as shown in Fig. 4. Shots ahead of the center are shown by open characters, and shots back of the center are shown by corresponding closed characters. From a study of the graph it will be seen that for shooting distances as great as 15 ft, first arrivals were through the upper soil, in which the velocity was 1,430 ft per sec. For shooting distances between 15 and 250 ft first arrivals were through a compact material in which the velocity was found to be 6,200 ft per sec. For shooting distances greater than 250 ft, the arrival times were shorter by way of the deep rock than through the overburden. The apparent velocity in the rock, V_u, when shooting from the "ahead" end of the line, or up-dip, is just twice as great as the apparent velocity, V_d, when shooting from the "back" end of the line, or down-dip. The true velocity in the rock, V_r, was determined by taking the harmonic mean of the apparent velocities and was found to be 16,400 ft per sec.

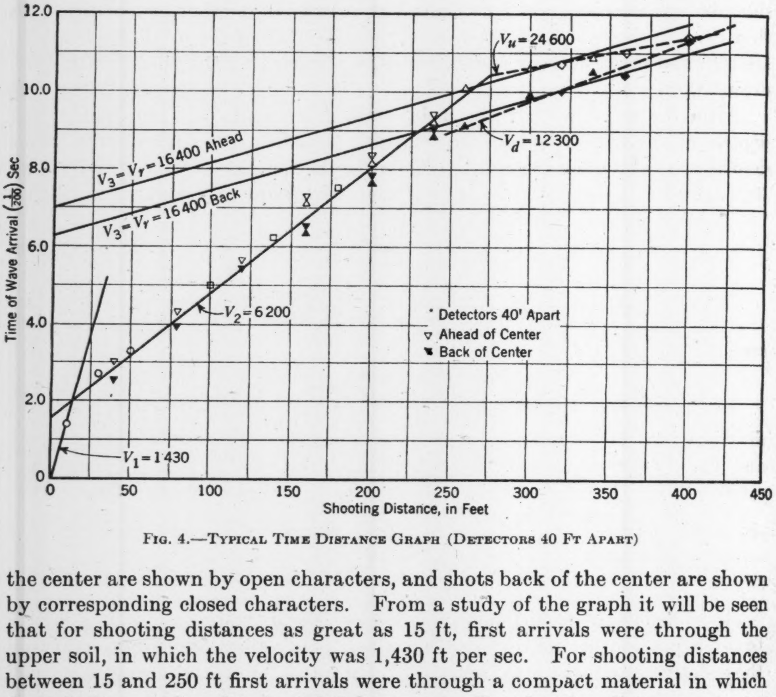

FIG. 4.—TYPICAL TIME DISTANCE GRAPH (DETECTORS 40 FT APART)

The depth of overburden at the center of the line was computed as follows, using the velocities previously determined and the approximate method for which Eqs. 2 are employed. The overburden depths are computed as follows: $V_r = \dfrac{2 \times 24{,}600 \times 12{,}300}{24{,}600 + 12{,}300} = 16{,}400$; $\sin \alpha = \dfrac{V_1}{V_2}$, and $\cos \alpha = \sqrt{1 - \left(\dfrac{V_1}{V_2}\right)^2} = 0.97$; and $\sin \beta_2 = \dfrac{V_2}{V_r}$, and $\cos \beta_2 = \sqrt{1 - \left(\dfrac{V_2}{V_r}\right)^2} = 0.925$. Then:

Computation	Feet
By Eq. 2*a*, $H_1 = \frac{1.6 \times 1,430}{400 \times 0.97} =$	5.9
One half the shot depth $= \frac{3}{2} =$	1.5
Depth of upper soil =	7.4
By Eq. 2*b*, the depth of till, H_2 (ahead) $= \frac{5.34 \times 6,200}{400 \times 0.925} =$	89.5
Depth to rock (ahead) =	96.9
Similarly, since H_2 (back) = 77.5, the depth to rock (back) $= H_{1+2}$ (back) =	84.9
The average depth to rock at the center $= \frac{96.9 + 84.9}{2} =$	90.9
Elevation, top of ground =	238.1
Elevation, top of rock =	147.2

From the computations it will be seen that the depth of the upper-soil layer, H_1, in which the velocity of wave propagation was 1,430 ft per sec, is 7.4 ft; T_1 in this instance is the interval on the time axis between the origin and its point of intersection with the V_2 limb of the graph, or 1.6; H_2 (ahead) or the thickness of the glacial till under the "ahead" end of the line was found to be 89.5 ft; and T_2 in this case is the difference between the intercepts of V_3 (ahead) and V_2 on the time axis, or 5.34. Similarly, H_2 for the back half of the line was found to be 77.5 ft. The total depths of overburden ahead and back are 96.9 and 84.9 ft, respectively. The depth at the center is assumed to be the average of these two values, or 90.9 ft. Theoretically any depth is determined by taking one half the sum of the depths at the shot point and the detector or receiving point, neither of which depth is known. The recorded depth for any line was the average of the mean or normal depths so determined for the two ends of the line. Because of the prevalent variation between the apparent and true velocities in most of the areas investigated, it was believed unwise to attempt to determine slopes in the rock surface from apparent velocities or to predict multiple rock elevations along a shooting line, and only one rock elevation on each line has been recorded in the final analysis of the data. The recorded elevation was designated as that at the center of the line.

Determination of Overburden Conditions.—In most locations considerable success was attained in classifying the overburden with respect to hardness and compaction as well as in determining the elevation of the top of rock. In areas where the characteristics of the overburden were generally known, the seismic data were useful in estimating the depths of individual strata. The seismic data have been used in studies of overburden conditions at structure sites and where excavations will be made for proposed hydraulic cuts and navigation channels.

From a correlation of drill records and seismic data over the entire project, the range of velocities for the various types of overburden was determined. In the areas investigated, velocities of 1,000 to 2,000 ft per sec generally indicated very loose material; velocities of 3,500 ft to 5,000 ft per sec usually were indicative of relatively soft material such as silt or clay; but in some instances velocities from 4,000 to 5,000 ft per sec did indicate fairly loose deposits of glacial till. Velocities in excess of 5,000 ft per sec usually indicated the presence of compact glacial tills.

In a large proportion of the test locations, two types or conditions of overburden exist as shown in Fig. 4. On the till ridges, velocities usually ranged from 1,000 to 2,000 ft per sec, to depths of from 5 to 8 ft. This zone of loose material is indicated by the steep portion of the graph (Fig. 4) through the origin. Beneath this zone of loose material, the velocity usually changed to a much higher value, the magnitude of which depended on the character of the material. Along the margin of the river and also in the bed of the river, overburden of a single velocity was often found. In some locations, three types of overburden were found, as shown in Fig. 5:

Soil type	Feet
Upper soil, H_1	5.1
Clay, H_2	12.5
Till, H_3	71.7
Depth to rock	89.3

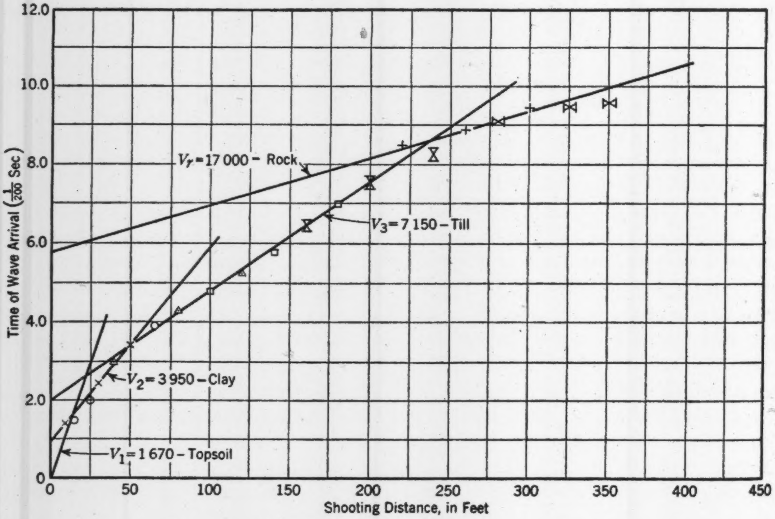

FIG. 5.—TYPICAL TIME-DISTANCE GRAPH SHOWING THREE TYPES OF OVERBURDEN

The soil profile as indicated by such graphs may not always be recognized in drill logs or by visual inspection, as velocity characteristics are determined by the depth of frost action, compaction, and other factors which may not appear from sampling.

Failure to Identify Shallow Rock.—In one section of the Point Rockway Canal area difficulty was encountered in identifying, properly, the hard rock that is within a few feet of the ground surface. In the analysis of the observed data, the intermediate material ($V_2 = 5{,}000$ ft per sec) was believed to be clay or till, although the irregularity of the data threw some doubt on this interpretation, and indicated the possible presence of a zone of seamed or fractured rock. Upon checking with the drill, relatively sound cores were obtained in this zone. A comparatively low velocity of 5,000 ft per sec for shallow and fractured rock is not uncommon in other formations but because of the unusually sound character of the rock previously encountered in the St. Lawrence River investigations, this condition was not anticipated. The low velocity was probably the result of seams opened by frost action and the absence of a heavy overburden load. Under a heavy overburden it is believed that this rock would have exhibited a much higher velocity.

To further investigate and study this irregularity found in the Point Rockway Canal, experimental seismic tests were made in the vicinity of the Northern Quarries near Norfolk, N. Y. At the quarries, where the rock face was exposed, a fractured and weathered zone could be seen to a depth of several feet. This rock was under a shallow overburden and was of the same origin as that in the Rockway Canal. The seismic tests adjacent to the quarries produced graphs very similar to those obtained from the data in the canal and showed that, under some conditions of fracturing, very shallow rock cannot always be identified by the seismic method.

Effect of Frozen Ground.—As early as the middle of December, 1940, frost in the ground began to affect results in some areas, and by February it had penetrated to such a depth, in areas unprotected by deep snow, as to interfere seriously with the accuracy of interpretations. Accordingly, field work was suspended during March and April. As the velocity of wave propagation in frozen soil is much higher than that in normal or unfrozen upper soil, this

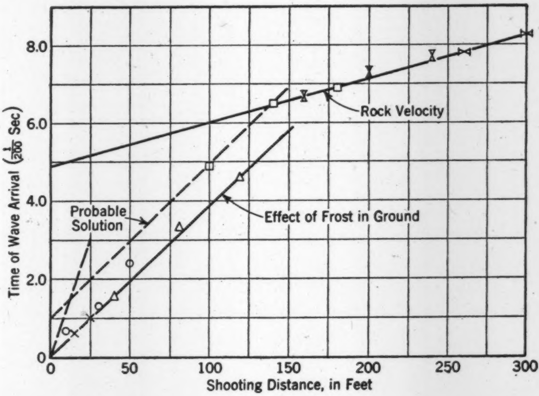

FIG. 6.—TYPICAL TIME-DISTANCE GRAPH SHOWING EFFECT OF FROZEN GROUND

condition leads to uncertainties in the interpretation of seismic data. The effect of 6 in. of frozen ground is shown in Fig. 6. Velocities of 5,000 to 7,000 ft per sec, values abnormally high for upper soil, were obtained for shooting distances as great as 100 ft. For longer shooting distances the crust of frozen ground did not carry sufficient energy to register on the film. Probable solutions were developed for many of the lines affected by frost. These were believed to be reasonably accurate, in regard to total depth of overburden, but their graphs are of little value for indicating the soil profile or character of overburden. Unfortunately many of the lines affected by frost were in areas of deep overburden where a knowledge of the overburden properties was of more importance than the depth to rock.

Subaqueous Exploration

Tests in Quiet or Slowly Moving Water.—The need for information on the character and depth of overburden in areas of the river channel where the water was quiet, or was moving slowly, called for the development of special equipment and a revised field procedure for under-water exploration. One of the essential requirements in making seismic tests on the bed of a river or other bodies of water is to provide means for placing detectors and shots with reasonable accuracy at predetermined locations. Another requirement is to waterproof the detectors and so mount them that they will assume a vertical position when lowered to the bed of the stream.

To place the shots and detectors accurately a float or marker line was constructed by attaching wooden blocks at designated points on a rope approximately 600 ft long. Measured from the center of the line, floats were attached at the following points: 0, 10, 40, 80, 130, 180, and 230 ft ahead and 0, 25, 40, 80, 130, 180, and 230 ft back. The center float, and those at 40 ft on either side of the center, marked the detector positions, and the other blocks marked the shot points as on a normal land line.

One end of the float line was anchored on the bed of the river at the upper end of the seismic line along which information was desired. A heavy stone usually served for this purpose. The line was then allowed to float downstream until it assumed a stable position. Where the current was not sufficient to stretch the rope, both ends were anchored after maneuvering the line into the desired position. In some instances it was necessary to anchor the center of the line also to prevent it from drifting with the wind or current. Buoys were attached at anchor points, when necessary, to keep the markers afloat. Empty oil cans of 2-gal or 5-gal capacity were found satisfactory for this purpose.

Two methods were used to keep the detectors in a vertical position on the bed of the stream. For depths of water not in excess of 10 ft the mounting shown in Fig. 7 was used. Each detector was provided with a waterproof housing made from a 10-in length of 3.5-in. pipe. The lower end was closed with a steel plate and the upper end with a cap containing a ¾-in. pipe nipple. In assembling the system the detector was placed in the housing and a pair of rubber covered auxiliary leads about 30 ft long were attached to the terminals. Cotton waste was packed around the sides of the detector and over the terminals, after which the leads were passed through the nipple and the cap tightly screwed on. It is important, of course, that the detector rest firmly on the bottom of the housing.

After stretching and anchoring the float line the three detectors were set at designated points. A pipe or rod was driven at each detector position and the detector assembly lashed to it in a vertical position. A boat containing the receiving apparatus was anchored about 50 ft from the center of the line and the three pairs of detector leads used in land work were connected to the auxiliary leads. A rock was tied to a piece of flagging or burlap to act as a sinker for the charge, and the cap wires were spliced to the firing line, which, in turn, terminated at the receiving instrument. The charge was then lowered to the bottom, after which it was detonated as in land practice.

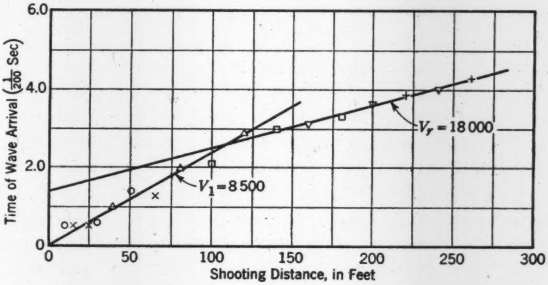

FIG. 9.—TYPICAL TIME-DISTANCE GRAPH OBTAINED WITH THE TRIPOD DETECTOR MOUNTING UNDER WATER

Where the water was more than 10 ft deep, the detector, in the same waterproof housing as that described, was suspended from the apex of a heavy iron tripod, as shown in Fig. 8. After sealing the nipple against the entrance of water the entire assembly was lowered to the bed of the river by a rope. The detector assumed a vertical position irrespective of the configuration of the river bed. Although it did not rest directly on the bottom it received the shock from the explosion through the legs of the tripod and the suspension wire. No difficulty was encountered in obtaining satisfactory records with either type of detector mounting.

A typical graph obtained by under-water exploration is shown in Fig. 9, the depth to sound rock in this case being $H = \frac{1.4 \times 8{,}500}{400 \times 0.88} = 33.8$ ft. This is an excellent graph and typical of most of those obtained in quiet or slowly moving water. In fact, the results are considered more accurate than those obtained on land, since, due to erosion, the overburden was more uniform in character, and usually a two-layer graph was obtained. The main source of error compared with the procedure used on land is in the placement of the charges in deep or moving water. It was found that under these conditions, the charge might drift a considerable distance before reaching the bottom, and allowance had to be made for this effect. Large errors in the placement of the shot, especially for the shorter shooting distances, will result in inaccurate time-distance graphs. Fortunately, where allowances had to be made for the drift of the charges, the overburden conditions were quite uniform so that the results from the shorter shooting distances were not needed for accurate interpretation.

Tests in Swift Water.—Seismic tests were made in the river channel area at the Long Sault Dam site where swift water made drilling too expensive to be included in the present program of exploration. The Long Sault Dam site is located at the foot of the Long Sault Rapids and the proposed dam site extends from the New York mainland to the head of Barnhart Island. Drillings, as shown in Fig. 10(*a*), were made on the shores of the mainland, on Barnhart and Long Sault islands, in the south channel where floats could be used, and on the shoal in the middle of the channel. The information obtained by drilling was very limited along the full extent of the axis of the dam. Soundings in the river channel made several years ago indicated that a rock gorge might exist at the site, especially between the shoal and Barnhart Island. As further drilling operations along the proposed axis of the dam would require large floating equipment and would be very expensive, seismic explorations were made wherever possible. It was found impracticable to make tests between the shoal and Barnhart Island where the velocity of the river is approximately 12 miles per hr and power boats cannot be maneuvered satisfactorily. A limited number of tests were made below the shoal and in the vicinity of the axis of the dam between the shoal and the mainland where the velocity of the river is not so great. Fig. 10(*b*) is a photograph of the river, taken from the New York mainland looking toward Barnhart Island, which shows the condition of the water in the area investigated.

In undertaking seismic exploration in the channel area it was realized that the usual accuracy could not be obtained and that the exploration would not

cover the area between the shoal and Barnhart Island. Nevertheless, it was believed that results could be obtained which would give the approximate elevation and configuration of the bedrock in the area explored, and even indicate the trend of the rock floor in the unexplored area. As it was impossible to place detectors on the river bed in excessively swift water, it was necessary to develop a procedure different from that used in quiet water. Fig. 11 illustrates the arrangement of apparatus used in these tests. A single detector and the oscillograph recorder were placed on shore close to the region to be explored. The detector was placed near a drill hole or seismic line where the depth to rock was known. The velocity in the adjacent overburden was determined in the usual manner. Single charges of dynamite were then placed with a float or boat at points on the river bottom and fired as in land practice.

One group of shots (S-3674 to S-3680, inclusive) were placed and fired while the detector was at drill hole D-1059. The locations of these shots are shown in Fig. 10(*a*). The firing line and a heavy sinker were attached to the charge which was then carried out in the river and dropped. The location of the charge, when dropped, was determined by two observers with transits. If possible, soundings were taken at the time of dropping the charge; otherwise the approximate elevation of the river bottom was determined from a map showing the subaqueous contours in the vicinity. The application of this method was limited, owing to the difficulty of handling the firing line in swift water.

Another group of single shots, S-415 to S-418, inclusive (also shown in Fig. 10(*a*)) were placed and fired while the detector was on the shoal in the channel, 120 ft from drill hole D-1364 and at the center of the line S-414. The firing line and a heavy sinker were attached to the charge which was then placed on a float made of two oil drums lashed together. The float attached to a cable was allowed to drift downstream with the current but was controlled by a winch mounted on the shoal. To keep the firing line from fouling, it was threaded through rings on the cable. When the float was at the desired location, a boat came alongside and the charge was released and dropped into the river. The location of the charge was determined by observers on shore. The float was then pulled 50 to 100 ft upstream and the shot fired. The depth of the river at the location of the shot was determined by actual soundings or from the map showing the subaqueous contours.

The method of analyzing the data obtained in the swift water at the Long Sault Dam site differed from the usual method of analysis as the knowns and unknowns were different and the necessary assumptions more radical. Referring to Fig. 12, the only information obtained from the film record was the total time, T, which elapsed from the shot instant to the arrival of the shock at the detector, D, Fig. 11. This total time T includes: t_1, the time of transit through the overburden at the shot S; t_2, the time of transit through the rock from B to C, Fig. 11; and t_3, the time of transit through the overburden CD. The value T was plotted on the time-distance coordinates at Q for the shooting distance OR, as shown in Fig. 12. As the velocity in the rock was known from previous tests on shore, it was possible to draw the line QM which gives PM or t_2 as the time of transit in the rock. As the depth CD was known from boring and seismic records, and the velocity, V_1, of wave propagation in the overburden from seismic tests on land, it was possible to draw line ON as t_3, the time of transit in the overburden at CD. This left MN, or t_1, as the time consumed in the overburden SB. To compute the depth H, or SB, it was necessary to assume the same overburden velocity there as at CD.

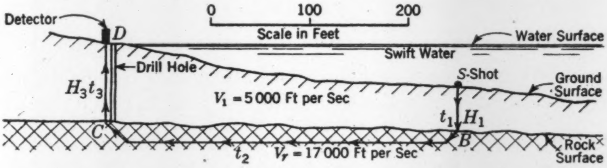

FIG. 11.—ARRANGEMENT OF APPARATUS FOR DETERMINING DEPTH OF OVERBURDEN IN SWIFT WATER

The results, as obtained from shooting in swift water, contain certain probable inherent inaccuracies. The assumption that the velocities in the overburden and rock in the river channel are the same as those determined on the adjacent land could be in error. However, any error resulting from this assumption will be only in proportion to velocity variations from place to place in the respective media. A more likely source of error is that in obtaining the true value of t_1. Where the depths to be measured are not great, the value of t_1 is small in comparison with T, and any errors in determining t_2 and t_3 will be carried into t_1 and may seriously affect its accuracy. Another source of error is in the determination of the shooting distance. With the velocity ratio of 17,000 to 5,000 ft per sec for rock and overburden as shown, an error of 3.4 ft in the shooting distance will result in a 1-ft error in H_1. The accuracy in determining the elevation of the rock also depends on the accuracy of the sounding of the river bottom. For large values of H_1 these errors are relatively small, but where attempts are made to measure shallow overburdens in this manner the indications may be entirely misleading. The data and conditions of the tests in the rapids have been analyzed and studied carefully and, although

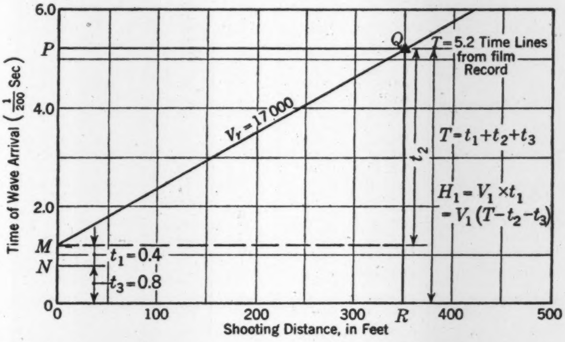

FIG. 12.—ANALYSIS OF OBSERVATIONS FOR DETERMINING DEPTH OF OVERBURDEN IN SWIFT WATER

limited in accuracy as to the actual thickness of the relatively shallow overburden in the bed of the river, it is believed that the results are reliable as indicating the trend of the rock contours and in precluding the possibility of a deep gorge in the area explored.

CORRELATION OF SEISMIC AND DRILLING RESULTS

The correlation between seismic information and drilling data has been thoroughly investigated over the entire project. Table 1 contains the seismic and drilling data at all locations where a drill hole was close enough to the center of a seismic line for a significant comparison to be made. In a few locations drill holes were spotted at or near the centers of seismic lines for the express purpose of checking the seismic predictions. This is true for lines 203 and 246 on Galop Island, lines 318, 320, 323, and 325 in the Rockway Canal area, and line 412 on Long Sault Island. On Galop Island the checks were remarkably close, being 1 ft in a depth of 42.3 ft and 1.5 ft in a depth of 54.0 ft, respectively. At line 412 there was a discrepancy of 11 ft in a total depth of 88.6 ft, which is believed to be the result of a very compact overburden condition immediately above the bedrock surface. Correlations in the Rockway Canal area were not entirely satisfactory, owing to the conditions previously described. At line 269, near the Massena Power Canal intake, there was an error of 9.9 ft in a

[a] To top of fractured rock. [b] To top of sound rock.

depth of 67.2 ft. Failure at this location to determine the depth of rock more accurately was the result of an artificial fill of varying depth created by the dumping of spoil from the excavation of the power canal. It should be noted that in all three of these locations, where the correlations are not satisfactory, the drillings were made to check apparent inconsistencies in the seismic data. With the exception of lines 269, 412, and a few of those in the Rockway Canal area, the correlations in Table 1 are quite satisfactory and indeed much better than obtained ordinarily in geophysical explorations.

The differences in depths of overburden, as determined by the two methods, are with few exceptions within the limit of the relief in the rock surface. For the greater depths the differences are relatively small, while for the shallower overburdens—such as at lines 89, 164, 175, 323, and 325—the actual differences, although only a few feet, may represent a large percentage of error. It should be remembered, however, that in all cases the drill record gives the depth of the overburden at one precise location, whereas the seismograph records an average depth over a considerable length of line.

Significance of Investigations

Heretofore the seismic method of exploration usually has been considered primarily applicable for making preliminary or reconnaissance investigations and has not been used extensively for making more detailed analyses. As a guide to drilling and for obtaining comparative data it has been of considerable value on alternate dam and spillway sites investigated by the U. S. Corps of Engineers. After a site for a structure has been definitely selected, it is customary to obtain detailed information by drilling. On the St. Lawrence River Project, the seismic data have been used more extensively than is generally feasible. All proposed cuts and channels were explored primarily by seismic methods, a few drill holes having been added to determine overburden conditions and to verify seismic results where bedrock occurred above or near excavation grade. The results have been used to a large extent in fixing locations and grades for the proposed cuts and channels in an effort to minimize the excavation of ledge rock. Other sites were explored with a small number of seismic lines to supplement the drilling program.

The use of the seismic data has enabled the design of concrete structures, navigation channels and hydraulic cuts to proceed more rapidly under the present program than if exploration consisted only of drill holes. A total of 355 satisfactory seismic determinations, and 47 of fair reliability, were made on land and in quiet water. To make the same number of rock elevation determinations by drilling, it would have been necessary to drill approximately 15,600 ft. The cost of such drilling would have been about four times that of the seismic investigations, an amount too great to have been included in the exploration program. Also the cost of additional drilling in the channel at the Long Sault Dam site would have been prohibitive. Although seismic tests could not be conducted over this entire swift-water area, the few results obtained were useful for design and estimate purposes.

Seismic determinations are valuable depending upon their accuracy in comparison to that required for the study of each feature. The accuracy, in turn, depends upon correct interpretation of the data obtained in the field. Reliable results can be obtained only by an experienced interpreter who understands the geological and surface conditions affecting the data. In general, the subsurface conditions were ideal for the seismic method and the results could be used with greater assurance, therefore, than in areas where conditions are more variable. The results of the seismic and drilling exploration were plotted on the various site maps, after which rock-surface contours were drawn. Although only one rock determination was computed for each line, the graphs often could be used to indicate the direction of slope of the bedrock surface. The results of the determinations at Long Sault Dam site, although not considered as accurate as other measurements, definitely indicated that if a bedrock gorge does exist, it is confined to the narrow area between the shoal and Barnhart Island.

The results of the investigation were very useful in interpreting overburden conditions, particularly in the areas of channels, cuts, and canals. By correlation with drill-hole data and the general geology of the region, the results aided in determining the extent and depth of various deposits of glacial till and other types of overburden and also their condition of density and compaction.

The subaqueous tests are believed to be unique for obtaining information of the type required for this project. Reliable results were obtained where detectors could be placed on the river bottom and sufficiently accurate results for required purposes were obtained in part of the channel area at the Long Sault Dam site where the water is swift. As the results of subaqueous exploration were satisfactory on this project, the use of the seismic method should be broadened in future investigations to include similar conditions.

Acknowledgments

The seismic investigations were made under the direction of Col. A. B. Jones, M. Am. Soc. C. E., district engineer of the St. Lawrence River District. Credit is due to F. P. Fifer, M. Am. Soc. C. E., head engineer on the project, for helpful and encouraging advice, particularly in regard to the subaqueous tests; A. E. Wood, associate geologist in the Binghamton District, supervised the work and analyzed the data during the early period of the investigation; G. R. Butterfield, Jr., Jun. Am. Soc. C. E., assistant engineer, rendered valuable assistance in laying out the seismic program and correlating it with the drilling program, and also in the final preparation of this paper; W. A. Wells assisted throughout the investigation in the interpretation and analysis of the field data and also in the preparation of the final report.

DISCUSSION

R. Woodward Moore,[5] Esq.—The application of refraction seismic tests to shallow explorations in water-covered areas constitutes a distinct forward step in the use of geophysics on civil engineering projects. This method of test already has proved to be a useful tool in connection with subsurface explorations for dam sites, highway grading projects, rock quarry sites, and tunnel locations. Data concerning foundation conditions at bridge abutment locations have been obtained with seismic tests, and, by means of subaqueous tests such as are described by the authors, it should be possible to investigate pier locations as well. The value of the application of the seismograph to bridge site explorations should not be underestimated, particularly in preliminary surveys for highways through undeveloped areas not adequately served by existing roads or trails. At times, a rapid survey of subsurface conditions using the seismograph may eliminate the need for further check tests using the more costly and time-consuming core drill or test pit. Although the exploration costs for a bridge structure may be relatively small, the ratio of cost of exploration to total cost of the structure may be relatively large in comparison with that for a large dam or reservoir.

In connection with the tests on land in the Point Rockway Canal area where the drill located a solid rock formation with a shallow overburden and where the seismic data were inconclusive, it would have been informative to have made additional seismic tests with the detectors and shot lines at right angles to the lines that were used. In one or two instances in the writer's experience appreciable differences in wave velocity (3,000 to 4,000 ft per sec) have been obtained when shooting two lines of tests oriented 90° with respect to each other. One location where such differences in wave velocity were found was near the bank of a small river. It is possible that early stream action exposed the ledge rock to the elements, which resulted in weathering characterized by vertical jointing or fracture zones. This is entirely suppositional since no rock was exposed at the surface at this location. Concealed by a mantle of soil deposited during subsequent periods of erosion, these fracture zones would tend to lower the wave velocity in the rock for seismic tests made along lines transverse to the weathered zones. Tests along lines parallel to the fracture zones would result in wave velocities characteristic of a fairly solid, continuous mass of rock.

With respect to seismic tests made on frozen ground, probably a carbon-button type detector such as was used in the tests on the St. Lawrence River Project, and which has been used by the writer, could be adjusted to such a degree of sensitivity that the first impulse or wave through the frozen ground would produce a relatively small break in the oscillograph trace. The slower but stronger impulse passing through the normal soil below the frozen zone then would be present on the oscillograph record as a "second event" which could be interpreted as the true time of wave travel from the shot to the detector.

---

[5] Associate Civ. Engr., FWA, U. S. Public Roads Administration, Washington, D. C.

These "second events" have been used by the writer in the interpretation of seismic records which were obtained in areas where a low-velocity layer was underlain by a rather thin stratum having an intermediate wave velocity which rested upon solid rock. Fig. 13 shows a film record obtained with the carbon-button detector in which "second events" are shown rather clearly.

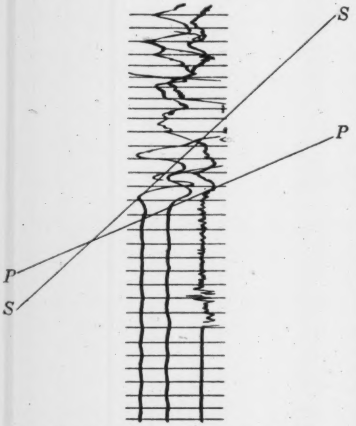

FIG. 13.—THREE-CHANNEL SEISMIC RECORD SHOWING PRIMARY (*P*–*P*) AND SECONDARY (*S*–*S*) WAVE ARRIVALS

Referring to the tests made "in quiet or slowly moving water," it would be interesting to know the actual velocity of the slowly moving water since there is some likelihood of water currents disturbing the detectors and causing troublesome vibrations which might mask the seismic wave coming from the shot. Research work may be required to determine the effect of various water velocities upon the submerged detector units, particularly where pipes or rods which extend to the surface of the stream are used. The effect of the flow conditions at the bottom of swift but deep water courses may require some remedial measures to assure a "quiet" detector should a satisfactory means of placing the units in swift water be developed.

In their analysis of the data obtained from the tests in swift water, the authors point out the probable sources of error in determining the elevation of the rock at the shot point in the stream bed. The average of the data from several shots at a particular point would tend to reduce the error in obtaining t_1 for the time of wave travel in the material overlying the rock. However, rock elevations obtained in the manner described should be useful in the design of dams and bridge piers.

In general, the accuracy indicated in a comparison of the rock elevations predicted from seismic data and those obtained from direct drilling, as given in Table 1, is in close agreement with the degree of accuracy obtained in similarly correlated tests made by the U. S. Public Roads Administration during the eight years since 1935. Usually the rock surface could be predicted within 5% to 10% of the true depth.

ARTHUR J. GRIER,[6] M. AM. SOC. C. E.—Considering how much has been written about geophysical exploration in the fifteen years since 1928, civil engineering literature is notably barren of references to the subject. It is difficult to explain why this laboratory technique, applied in the wide-open spaces, has had so little consideration by civil engineers and why they have made so few contributions to its development.

---

[6] Cons. Engr., Geophysical Exploration, Oakland, Calif.

Perhaps, too often, successfully applied geophysics has been publicized without due emphasis on the advisability of confirming favorable implications by more common and costly exploratory methods before undertaking large expenditures. Geophysics is essentially a technique of elimination by comparatively inexpensive methods to assure the largest amount of information at the least cost in time and money. Its results are highly indicative but should not be accepted as determinative. It is a most useful tool in the hands of those who hold that engineering is not averse to making a dollar earn the most interest.

The authors frankly state that the seismic program of the Corps of Engineers was intended to guide and augment the drilling program and that all was to be interpreted by the observed geology of the region. The physical data of the shock wave were to be correlated with and confirmed by the more common physical tests of applied optics and mechanics. This sequence is just as profitable in civil engineering as it is in mining.

Seismic geophysics is specially applicable to the study of slightly dipping formations such as those for foundations and oil structures. Steeply dipping contacts of quartz veins, dikes, and faults, found in mining and water supply problems, may be delineated rapidly and accurately by electrical methods based on a difference of resistance.

Since 1936 the writer has used an instrument which is simple, sensitive, and portable, based on an electrical circuit which he devised and has never seen described elsewhere. The fundamental circuit without refinements and reversing switches is shown in Fig. 14. This method employs a unidirectional electric field set up by means of common B batteries and two metal current electrodes marked C_1 and C_2. Within this imposed field are three equally spaced nonpolarizing porous cups containing copper sulfate solution in which are the potential electrodes P_1, P_2, and P_3. These cups establish in the ground the two arms of a Wheatstone bridge, the other two arms being within the instrument and composed of the two segments of the potentiometer rheostat P_R with a dial graduated 0 to 100. The field is made strong enough that the potential at P_2 is intermediate between that at P_1 and P_3.

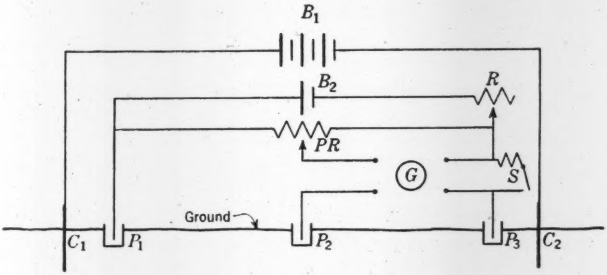

FIG. 14.—FUNDAMENTAL CIRCUIT

Without further provision a current would flow through these cups and the instrument, and the apparent resistance of the ground, in reality, would be the sum of the ground resistance plus the contact resistance at the potential electrodes, which might vary with each setup over the same ground. So it becomes necessary to employ the principle of the compensation bridge, or potentiometer, and neutralize the potential drop between P_1 and P_3 with an equivalent electromotive force from the battery B_2, adjusted by means of the rheostat R. Neutralization is indicated when the galvanometer G (which has been cut into that circuit) reads null, and since there then is no current through P_1 and P_3, there can be no contact resistance.

With the compensation bridge established, the Wheatstone bridge is effected by cutting the galvanometer over into the circuit P_2-P_R and closing the switch S with included resistance equal to that of the galvanometer. If the contactor is moved along the graduated meter wire P_R until the bridge is in balance, no current flows through the potential electrode P_2 and likewise there is no contact resistance at that point.

It remains only to read and note the two segments of the graduated dial P_R which accurately reflect the relative potential drop, and hence the relative ground resistance, of the two adjacent stations under consideration. There is but one instrument, the galvanometer, to be observed, and no mathematical calculations whatever are required.

The diagram does not show reversing switches, but it is necessary to reverse polarities and repeat the operation. The average of the readings will balance out the natural earth potential which usually will be encountered. That is the entire operation.

All electrodes, both current and potential, are moved ahead one station, and new readings taken as before. Upon the completion of the traverse, the notes plot a profile of relative earth resistance to a depth depending upon the spacing of the electrodes. Any anomalies become conspicuous, and such areas can be explored further by rerunning with different electrode spacing and by probing for depth at critical spots. It is observed that depth readings are much sharper when using the bridge circuit than when calculated and plotted in a curved line by the usual Wenner[7] formula. No attempt is made to determine specific earth resistance, and it is questionable if there is any advantage in doing so. Both methods are based on the same recognized laws pertaining to electric currents in a semi-infinite medium.

The entire subject of geophysics, including the several approved methods, may be regarded as an expansion into the realm of the unseen of the ancient science of surveying. It derives from a better knowledge of physical laws and is made possible by instruments of sensitivity and precision.

The economic value to civil engineering of this surveying of the unseen will be recognized as more field engineers with training in the physical sciences apply their skill to just such problems as the St. Lawrence River Project under discussion.

F.W. LEE,[8] ESQ.—A careful explanation has been presented in this excellent paper of the technique as well as of the results that can be obtained by the application of seismic refraction methods for securing subsurface information regarding depth to bedrock. Little can be added other than to compliment the authors for the accurate manner in which they have executed this project.

[7] "A Method of Measuring Earth Resistivity," by F. Wenner, *Bulletin No. 258*, U. S. Bureau of Standards.

[8] Chf., Div. of Geophysical Exploration, Bureau of Mines, U. S. Dept. of the Interior, Baltimore, Md.

Field observations made on Governors Island in the Boston (Mass.) Harbor have showed that, even under very simple geological conditions involving glacial drift, the speed in the drift is not uniform and that certain average values can be made to apply in each interval of observation. An attempt was made to chart such velocities in the glacial drift on the island.[9] Apparently, the ratio of gravel to clay in the drift is a factor. In water-sorted gravel beds, particularly where the individual stones all were worn into ellipsoidal bodies and deposited with their minor axes in a vertical position, the vertical and the transverse seismic velocities were not the same. However, the differences in boulder content overshadowed such observations.

In presenting this paper the Society has taken a very definite forward step in making surveys in three dimensions, combining parts under water with nonsubmersed areas. The good old transit which serves so well above ground has added a brother for looking down into the earth, which at present has the title of seismic methods of exploration. Of these the refraction seismic method has proved particularly helpful for the measurement of depths to bedrock, as can be noted from Table 1, which shows that the seismic depth determinations agreed with the drill-hole record to within a few feet.

The following information is given as a matter of caution for executives who may be planning other applications of seismic refraction methods. A controlling feature of seismic methods depends upon the depth to which measurements are made, in conjunction with the accuracy of the final information expected. These various projects may be divided according to the depths of observation into the following classes:

Class	Approximate depths, in feet	Description
1	100	Depth to bedrock required for dam foundations, bridgeheads, road construction, water sources, and excavations.
2	400 to 500	Depths to preglacial channels, required for some foundation work and for sources of water supply for cities and regions.
3	800 to 1,000	Geological stratigraphy related to the planning of subsurface tunnels such as would be required for dewatering mines and mining areas.
4	3,000	Identification of large geologic bodies such as salt domes in southern Texas and Louisiana, which are of economic importance because of the oil generally found on the top and on the flanks of such domes.
5	> 300,000	Depths to regions of change in magmatic material, useful for earthquake studies and in the detection of major geologic changes.

---

[9] *Bulletin No. 8*, Dept. of Public Works, Boston, Mass.

The criterion of a seismic analysis is the degree to which a seismic impulse may be traced from the shot point to the detectors for the proper speeds as well as for the distances traversed in each medium. Mathematically, the formulas for refraction seismic surveys are very similar to those for geometric optics. They differ from those for optics in that they are used to analyze the material traversed instead of to design special surfaces of lenses for certain critical characteristics.

Often, even for very simple field cases, the solution becomes complicated since there is generally a weathered zone near the ground surface which has a comparatively small seismic speed of the order of 1,000 ft per sec. Directly under this weathered zone is a much faster unweathered zone having a seismic speed of the order of 5,000 ft per sec. Below it are the various geological beds each having a characteristic velocity—in granite and dense limestones reaching velocities of the order of 20,000 ft per sec. Therefore small differences in the thicknesses of the slow beds can introduce large time errors which, when applied to the same ray path in the fast beds, will introduce large errors in depths. To these differences must be added corrections for elevations for the various detectors on the shot line as well as for the variations of the topography of the bedrock. The cost of a project often depends to a large degree on the necessity of making supplementary seismic records for determining such irregularities singularly.

When making seismic surveys to a deeper horizon, the distances between the shot point and the detectors become increasingly greater, and the simple assumption that the segments of geologic beds over which the measurements are made may be considered as plane surfaces no longer can be maintained. The thickening and thinning of the intermediary beds make the analysis very slow and tedious. On encountering such difficulties, the field engineer making the seismic surveys uses overlapping and abutting traverse lines of observation for clearing out such singularities. After the field work is done, the results may be likened to a picture puzzle, each piece representing a seismic profile. These pieces must be fitted together into such an integrated whole as would be produced by the geological conditions in question. From this point the procedure becomes increasingly more complex with the addition of each intervening bed which must be taken into consideration. Also, the geological "quirks" which might be associated with each bed must be considered. In deep refraction surveys of the order of 1,000 ft, one often encounters as many as four or five characteristic beds, each of which must be defined and differentiated separately.

From the foregoing, it is evident that the path of a seismic survey engineer is a hard one. Nevertheless, such geophysical methods may be considered the first rays of a new branch in civil engineering for studying hitherto unsounded depths on a scale which may be called planet engineering. Upon the foundations established by such studies it is hoped that in the end mankind will be provided with a power of knowledge that will permit him to make this planet perform according to his will, in much the same manner as a violin in the hands of a master.

L. Don Leet,[10] Esq.—Considerable success in operations under sometimes rather difficult field conditions has been achieved by the authors. They are to be congratulated upon this application of the seismic method, which has established itself rather widely in recent years but is often anything but simple and straightforward in its execution.

In connection with the detailed discussion of methods perhaps it should be emphasized that the authors' system of shooting does not yield what are known as "reverse profiles." In other words, the observations along a line "ahead" of the detectors are based upon elastic waves which do not travel over a common path with those along the line "back" from the detector location. Structurally, the significance of this is that interpretations assume continuity and uniformity of the high velocity rock surface over a distance which represents the combined length of "ahead" and "back" profiles. In some regions such an assumption would lead to serious errors, but in the area covered by the authors' report this apparently was not the case.

Perhaps it is a small point to mention in connection with so excellent a paper, but in the interests of accuracy there seems to be no harm in pointing out that the formulas by which depths were computed are credited to Messrs. Ewing, Crary, and Rutherford (1937),[3] as they have been on previous occasions by Mr. Shepard. Actually, those formulas had been in use for approximately ten years before publication of the paper by Mr. Ewing and his assistants, and it is not correct to imply that they were developed first in 1937. At least one place where they had been published in 1931 was in the Bulletin of the French Bureau of Mines.

William L. Shannon,[11] Jun. Am. Soc. C. E., and Winthrop A. Wells,[12] Esq.—In connection with preliminary foundation investigation for flood control structures in the Merrimack Valley watershed, the District Office of the Corps of Engineers, Boston, Mass., made use of the Shepard type of seismograph to determine the elevation of bedrock. During the autumn of 1938, the proposed Riverhill Dam site[13] was investigated extensively and some work was done at the Franklin Falls Dam site. In the summer of 1939, seventeen proposed dam sites were investigated by the seismic method. At some of these sites, at a later date, drill holes were located and drilled at or adjacent to seismic lines. The results of both seismic and drill hole data are summarized in Table 2. The method used in these investigations is similar to that described by the authors under the heading: "Determination of Overburden Depth by Two-Way Shooting."

The seismic investigations at each site immediately followed a thorough geologic reconnaissance. The results of the geologic reconnaissance and seismic data were then used as a basis for selection of sites for more detailed study. At three of the proposed sites, detailed explorations of some areas by seismograph were made for final explorations to supplement drilling and aid in exact location of structures.

In general, the agreement between seismic and drill-hole determinations, as shown in Table 2, is not as good as that obtained at the St. Lawrence River Project. It is believed that, to a large extent, the greater disagreement is due to the presence in this region of one or both of the following: (1) A variable, relatively high velocity weathered rock above sound rock; and (2) a highly irregular rock surface.

[a] Distance from drill hole to seismic center.

The writers agree with the conclusions presented by the authors. Particularly is it desired to emphasize the usefulness of the seismograph for preliminary investigations for dam sites on the basis of relative cost, time required, and accuracy when compared with drilling.

E. R. SHEPARD,[14] ESQ., AND REUBEN M. HAINES,[15] ASSOC. M. AM. SOC. C. E.—The question of disturbance of detectors in moving water has been raised by Mr. Moore. Some disturbance was observed in relatively still water where the detectors were supported by iron pipes projecting above the water surface. This appeared to be the result of surface wind ripples against the supporting pipes. With the tripod type of detector support, where the detector and supporting structure were entirely submerged, the disturbance, even in flowing water, was surprisingly small.

The writers are indebted to Professor Leet for clarifying the record with respect to credit for the equations used in computing overburden depths. The paper does not refer specifically to the origin of the formulas but states that they are given by Messrs. Ewing, Crary, and Rutherford. They, in turn, do not claim originality but refer to the formulas as the standard method of interpreting refraction data. Reference was made to this article because the equations there appear in a simple and usable form and are readily available for reference.

[14] Senior Physicist, Corps of Engrs., U. S. Army, Washington, D. C

[15] Engr., Corps of Engrs., U. S. Army, Washington, D. C.

Reverse profiles, as described by Professor Leet, were actually obtained over the 80-ft distance between outside detectors. This 80-ft spread was a common path for waves through the rock from reverse shooting distances greater than the critical distance, beyond which the first arrivals are through the rock stratum. From such shots it was possible to compute apparent and true velocities in the rock directly under the 80-ft detector spread. It is true that the local velocity so obtained was assumed to prevail throughout the entire length of the seismic line. The small errors that might result from this assumption are usually minor in comparison with those referred to by Mr. Lee, involving small differences in the thicknesses of the slow beds which can introduce large time errors when applied to the same ray path in the fast beds. Because of this almost universally prevalent condition only one depth of overburden was recorded for each seismic line. The recorded depth was designated as that at the center of the line where the velocity profile in the overburden was determined most accurately.

In refraction shooting where a plurality of detectors is employed and a relatively few shots placed within the detector spread, the reverse profile through the fast beds is obtained only over a limited central portion of the line, the length of the common path depending on the depth of the overburden. If the overburden is deeper than a critical value depending on the shooting distances and detector spacings, it is possible that no common path will exist, and in such an event it would be impossible to compute the true velocity in the rock from the observed apparent velocities.

Mr. Grier describes a new and interesting modification of the well-known four-terminal electrical method of exploration. From a study of his circuit it appears that what the instrument actually does is to compare the potential drop $P_1 P_2$ with that of $P_2 P_3$. With a symmetrical distribution of the field current between C_1 and C_2, the potential ratio will be a measure also of the ratio of resistances $P_1 P_2$ and $P_2 P_3$. Mr. Grier does not say how far he places the current electrodes from the potential cups, but it is evident that, to insure a reasonably symmetrical distribution of the current in the ground, the current electrodes should be spaced equally from the respective potential cups P_1 and P_3 and at a sufficient distance from them to avoid the distorting effects on the field current of local variations in the resistivity of the top soil. These conditions are usually met, with the standard four-terminal arrangement of electrodes.

The writers are familiar with the seismic programs described by Messrs. Shannon and Wells. In Table 2, showing comparisons of seismic interpretations with drilling records, eight of the drill holes listed were not extended to rock. The only point at which the seismic and drill data appear to be seriously out of agreement is at the West Henniker Dam site where the drill reached the top of rock at a depth of 73.1 ft, and computations from seismic data gave a depth of 137 ft. The original records on this project have been consulted. The drill log for hole No. 9 reveals a soil profile as follows:

Depth, in ft	Soil
0 to 1	Top soil
1 to 11	Light gray, compact, silty fine to medium sand, with a trace of gravel
11 to 53	Grayish brown, compact, slightly gravelly, silty sand (glacial till)
53 to 70	Brown, compact, slightly silty fine to medium sand
70 to 72.6	Dark gray, compact, gravelly sand
72.6 to 89.3	(Bottom of boring) mica-schist, badly weathered to bottom of boring, over-all core recovery 32.5%

The seismic data at line 4 show the following velocity profile:

Depth, in ft	Wave velocity, in ft per sec
0 to 4.5	1,180
4.5 to 17.5	2,240
17.5 to 137	7,000
>137	16,550

It is evident that the velocity of wave propagation in the till and that in the badly weathered mica-shist were so nearly alike that it was impossible to discriminate between the two formations. No doubt other minor discrepancies shown in the table can be attributed to the same condition. It can be said for the seismic method that the weathered mica-shist, which is obviously unfit as foundation material for a masonry dam, did not register as sound rock. This instance is an excellent example of the limitations in geophysical methods of exploration and emphasizes the need for experience and sound judgment in the interpretation of all geophysical data.

Paper No. 2209

DETERMINATION OF KUTTER'S *n* FOR SEWERS PARTLY FILLED

By C. Frank Johnson,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Thomas R. Camp, Richard G. Coulter, C. E. Ramser, and C. Frank Johnson.

Synopsis

Kutter's formula is widely used in computations involving the hydraulics of sewers. The value of the coefficient of roughness, *n*, in this formula can be determined for sewers by only one method—making actual measurements of velocities (or discharges) and depths of flow in the sewers. The results of measurements made in pipes and conduits carrying clean water cannot be used for sewers without modification; however, they do afford a valuable guide. Unfortunately, records of determinations of the value of *n* for sewers are all too scarce.

This paper presents the results of certain determinations, based on field measurements, of the value of Kutter's *n* for sewers partly filled. The technique followed in making the field measurements is described, and a comparison is made between the various methods used for measuring the velocities of flow in the sewers.

Introduction

During extensive gagings of sewage flows in Louisville, Ky., in 1939–1940, field determinations were made of the velocities of flow and corresponding discharges in four sewers at various depths of flow ranging in different sewers from 0.03 D to about 0.4 D. From the results of these determinations Kutter's n was computed for each test run, and an average value determined for each sewer. Several conclusions based on the results of these determinations are given at the close of this paper. The one of most general interest, probably, indicates that the values of n for low flows in sewers are higher than the values for flows of greater depth. The fact that higher values of n obtain for pipes not substantially filled has been recognized for some time;[2,3] however, there is a scarcity of experimental data showing the actual values of n for sewers having low flows.

Note.—Published in February, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

FIG. 1.—CHARACTERISTICS OF SEWERS IN WHICH MEASUREMENTS WERE MADE

The measurements of velocities and discharges described herein were made on various dates during dry weather, when the sewage presumably contained no storm water; nor was there any ground water entering the sewers within the test reaches, according to available data. Although Sewer A (Fig. 1) was partly below the ground-water level, lead-strip water stops incorporated in the transverse construction joints prevented the entrance of ground water. The other sewers were above the ground-water level. It was assumed that the flows were not increased by ground water entering within the test reaches.

GENERAL TECHNIQUE

Velocities were measured by the dye-velocity (or color) and the salt-velocity methods. Each measurement was made by noting the time of travel of the dye or salt solution from the point of application to a downstream point of observation. The solution, after thorough mixing, was poured into the flowing sewage as rapidly as possible, and the average time of the application noted either on a stop watch or by the use of the second hand on an ordinary watch. Observations at the downstream point were made by the use of the same watch or another watch synchronized with the one used at the upstream point.

Dye-Velocity Method.—When using dye, the time of its appearance at the downstream station was noted visually, as was also the approximate time of the most intense color and the time when the dye could last be detected. The exact time of the appearance of the dye was easily determined, but the exact times of the most intense color and the last appearance of the dye were difficult to determine, because of the gradual changing or fading of the color at these times. Also, the natural discoloration of the sewage and the necessity for using artificial light in the sewers hampered these visual determinations somewhat.

The dye-velocity method has previously been utilized extensively for measuring velocities of both sewage and clean water and has been shown[4] to give results averaging within about 3% of those obtained by the use of carefully constructed weirs. The time of travel of the dye is generally considered to be the interval between the instant of introduction of the solution and the average time of the first and last appearance of the color at the downstream station.[4,5]

Salt-Velocity Method.—When using salt, the time of passage of the salt at the downstream station was determined either by the chemical method—that is, by titrating small samples of sewage taken at definite times—or by the electrical-resistance method, using electrodes immersed in the flowing sewage.

For the chemical or titration method, samples were dipped from the flowing sewage near the center of the sewer at a point just below the surface. Except on two runs, the samples were taken at 10-sec intervals, starting 1 or 2 min before the computed time when a pilot dye test indicated that the first salt should reach the downstream station and continuing until 1 or 2 min after the like computed time of the last appearance of the salt. The samples were titrated for chloride content, using standard methods with silver nitrate as a reagent and potassium chromate as an indicator. A graph of the chloride content of the sewage was then plotted, using time as abscissas and chloride content as ordinates. The center of gravity of the area included between the line of normal chloride content extended and the line showing increased chloride content was found by cutting out the area from a piece of cardboard and suspending it from first one point and then another, marking the center of gravity at the intersection of the directions of the suspending cord. Then, on the graph the position of the vertical through this center of gravity, called the centroid vertical, was plotted, the location of the centroid vertical being considered to represent the mean time of passage of the salt particles.[6,7]

---

[4] "The Flow of Water in Concrete Pipe," by Fred C. Scobey, *Bulletin No. 852*, U.S.D.A., 1920, p. 19.

[5] "Handbook of Hydraulics," by Horace W. King, 2d Ed., McGraw-Hill Book Co., Inc., New York, N. Y., 1929, pp. 372 and 373.

On the later runs, when using salt, the electrical-resistance method was used and found to be much easier, faster, and more satisfactory than titration of samples. Copper electrodes of 24-gage metal, 2 in. square, were mounted on a lead-weighted wooden strip at a spacing of about 1 in. apart. The electrodes were connected to one or more small dry cells, with a variable resistance in the line. Meters reading to 300 milliamperes and to 8 volts were used. The electrodes were suspended in the sewage, all other equipment and the observers being above ground. Readings of the milliammeter were taken at 2-sec or 5-sec intervals and were plotted in the same manner as the results of the titrations, previously described. The centroid vertical of the area of increased current resulting from the passage of the salt charge was taken to indicate the time of passage of the salt.[6]

The salt-velocity method has previously been used extensively for measuring the velocity of clean water in pipes under pressure and has been shown to give results, under such conditions, averaging only 0.32% in excess of a weir.[6] This method has been utilized for testing large pumps, after its accuracy had been verified by volumetric check runs.[8] However, the salt-velocity method does not appear to have been applied to a great extent for measuring velocities in sewers partly filled.

Depth-of-Flow Measurements.—For each test the depth of flow of the sewage was ascertained by measuring from a previously established reference mark or grade nail, set above the water at a known short distance above the sewer invert, to the water surface. This measurement was subtracted from the height of the reference mark above the invert. The height above the invert of each reference mark was determined in advance by measuring the flow depths of the sewage at several points in the vicinity, by averaging these, and by adding to the average depth the distance from the reference mark to the water surface at the time.

In Sewers A, C, and D (Fig. 1), the depths for the tests were measured at the downstream end of the reach, check measurements having indicated that the depths so determined represented the mean depth in the reach. In Sewer B, however, it was necessary to measure the depths at the upstream and downstream ends of the reach, as these depths varied as much as 0.07 ft; in this case, the average areas and average wetted perimeters were used.

Determination of Slopes.—The slope of the water surface in Sewers A, C, and D was considered to be the same as that of the sewer, because the check measurements previously mentioned had indicated that this was substantially correct. After they were checked by levels run in the field, the nominal slopes of these three sewers were used. However, in the case of Sewer B, the measured slope of the water surface (corrected to the slope of the energy gradient on two runs where the correction was as much as 0.01 ft) was utilized.

Determination of n.—Based on the velocities determined in the sewers, computations were made of the value of C in the Chézy formula:

$$V = C\sqrt{RS} \qquad (1)$$

in which V = velocity, C = coefficient, R = hydraulic radius, and S = slope of the energy gradient (or water surface). The results of these computations furnished data for the determination of Kutter's n by the use of tables in standard handbooks.

FIG. 2.—SEWER A, BEFORE BEING PUT INTO SERVICE

SEWER A

Description and Condition of Sewer.—Built in 1932, Sewer A is part of the Southwestern Outfall. Within the test reach the sewer is straight except for one curve which has a radius of 100 ft and which is 14 ft long. There are no "live" inlets within the reach. The invert is unlined concrete except for three stretches each 13.5 ft long, which are bricklined; and the concrete of the invert (up to the springing line) was originally poured against steel forms.

At the time of the tests the condition of this sewer was excellent in every way (see Fig. 2). The concrete of the invert was very smooth, being considerably better than average in this respect, and there was no deposit on the invert. The evenness of the grade was shown by a profile of the invert, and by measured depths of flow, which had a maximum variation of only 0.10 ft within the test reach at any one time. This was not considered excessive for such a large sewer.

Parshall Measuring Flume.—The dye-velocity and salt-velocity methods were checked in this sewer by use of a Parshall measuring flume[9] which was in place at the upstream end of the test reach. The check was made to ascertain just what stage or time of the passage of the dye or salt should be used for determining the mean velocity for these particular tests and to check the accuracy of the methods used.

The flume was so constructed that "free-flow" conditions were secured, necessitating the measurement of only one head, H_a, to determine the discharge. For each test, the head was measured immediately after pouring the solution into the sewage.

[9] "The Parshall Measuring Flume," by Ralph L. Parshall, *Bulletin No. 423*, Colorado State Coll., Colorado Experiment Station, Fort Collins, Colo., 1936.

The velocities determined by use of the flume, and the corresponding values of Kutter's *n*, are shown in Table 1(*b*). A comparison of these velocities with those determined by use of dye and salt is given in Table 1(*c*). (In Fig. 3, Test No. A-4: B = beginning of increased chloride content; P = peak of salt content; E = end of increased chloride content; *M* = mean time of salt appearance; and the line BE is the line of normal chloride content.)

E.[9] [k] Velocity of flow in the sewer, $= \frac{\text{Col. 10} - \text{Col. 19}}{\text{Col. 19}}$. [n] $\frac{V_c - V_f}{V_f} = \frac{\text{Col. 11} - \text{Col. 19}}{\text{Col. 19}}$. [o] $\frac{V_m - V_f}{V_f} = \frac{\text{Col. 12} - \text{Col. 19}}{\text{Col. 19}}$.

It will be observed that in Table 1(*c*) no comparison is shown for Test No. A-3. The results of this test are viewed with some question for two reasons: (1) The head on the flume (0.28 ft) was very near the recommended minimum[9] for a 5-ft flume; and (2) it appeared that some of the salt solution might have been retained unduly long at the point of application. This point was located at the downstream end of the flume, where some of the dye on a preceding test (which was rejected) had been retained for a short time, by eddies in the sewage flow. Furthermore, the chloride-content graph for Test No. A-3 (Fig. 3) is very flat after passing the peak, apparently from the same cause. This difficulty was obviated on the other tests by pouring the solution into the sewage at a point approximately 40 ft downstream from the flume.

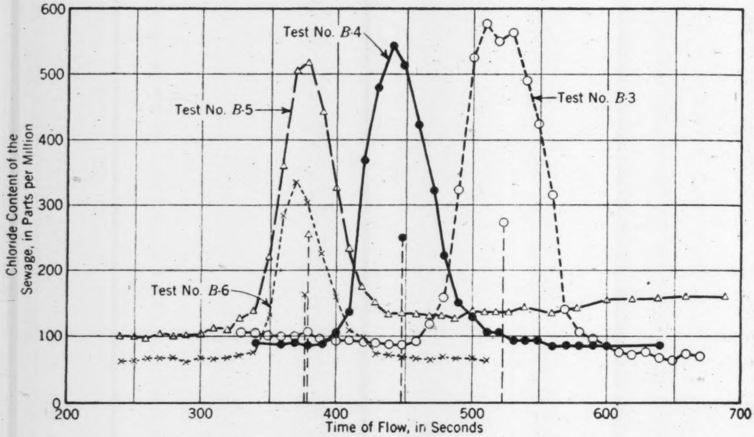

FIG. 4.—TITRATION OF SEWAGE SAMPLES FROM SEWER B

The comparison shown in Table 1(*c*) indicates a satisfactorily close check for the purposes of the gagings being made, the use of the centroid vertical on Tests Nos. A-4 and A-5 indicating velocities averaging 4.4% in excess of those obtained by use of the flume. According to Mr. Parshall,[9] the accuracy of discharge measurements made with the Parshall measuring flume is within 2% to 5%, under normal operating conditions. A closer check between the flume measurements and the dye and salt measurements might have been secured during the tests by taking the sewage samples for titration from some point in the cross section other than near the center of the sewer, say, at or near the quarter point. As the samples were taken near the center of the sewer, however, the computed velocities may be as much as 2% to 5% in excess of the respective true mean velocities, because there is some chance that only the fast water was thus timed. Such difference has been found when using the salt-velocity method in this way for measuring velocities in pipes entirely filled.[6] For these reasons, the velocities determined by use of the centroid vertical of the salt tests, made as described herein, seemed slightly above the true average velocities, and the resulting values of *n* were therefore slightly low. It was thought that these values of *n* were as much as, say, 2% to 5% low. (This possibility should be kept in mind when studying the results of the tests.) The use of a slightly low value of *n* was not objectionable from the standpoint of the purpose of the sewage gagings being made—to obtain data upon which to base the design of intercepting sewers and a sewage-treatment plant—as the computed discharges would then be slightly, but not significantly, on the high or safe side.

In addition to the other considerations, the results of the salt-velocity tests, rather than those of the dye-velocity tests, were used for the determinations of the mean velocities and the values of *n*, because the salt method affords more tangible data and gives more definite and satisfactory results than the dye method. For this reason, and, as a result of the comparisons made and discussed in the preceding paragraph, these determinations were based on the centroid vertical of the salt tests.

The dye tests were necessary in some instances as pilot tests, however, particularly when using titration of samples, and were of value in all instances as check observations. When the color method is used exclusively, the mean time of the dye appearance would probably indicate the mean velocity most satisfactorily.

Use of the centroid vertical for the salt tests and the mean time of the dye appearance for the color tests is in accord with the recorded practice of others.

Value of n.—Based on the centroid vertical, the average value of Kutter's *n* for Sewer A, at the extremely low depths of flow encountered, is 0.0140. The value of *n* for this sewer when substantially filled is probably 0.0130 or lower.

SEWER B

Description and Condition of Sewer.—Sewer B is part of the Southern Outfall, built in 1909. Within the test reach the sewer is straight, with one 15-in. inlet. However, no water seemed to be discharged by this inlet during the tests. The entire inside surface of the sewer is unlined concrete and, according to a report of the commission supervising its construction, "steel forms were used [on the side-walls] * * *, the invert having a troweled finish equivalent to that ordinarily given sidewalks."

At the time of the tests the condition of this sewer was good and the concrete surface fairly smooth, but not as smooth as the concrete of Sewer A. An inspection of the entire stretch, made about two years prior to the time when the velocity measurements were made, revealed that "most of the invert is free from deposit and is slippery"; however, a deposit about ½ in. deep was reported at the center of the sewer at three points within the stretch. At the time of the tests, conditions appeared to be substantially the same as when the inspection was made.

General Results.—The results of the titration of the sewage samples taken in Sewer B are shown graphically in Fig. 4, and in Table 2(*a*) are given the principal data and the results of all the tests conducted in this sewer.

The values of *n* based on the individual tests in this sewer are not so consistent as might be desired. This may be the result of a considerable deposit on the invert of the sewer at a point approximately 900 ft downstream from the test reach. The deposit acted as a low dam, causing the previously mentioned variations in the depth of flow within the test reach.

Value of n.—Based on the centroid vertical the average value of Kutter's *n* for Sewer B at the depths encountered is 0.0144. The value of *n* for this sewer when substantially filled is probably about 0.0130.

SEWER C

Description and Condition of Sewer.—Built in 1908, this sewer is part of the Beargrass Intercepter. Within the test reach the sewer is straight for only about one third of its length. However, the curves are of such long radii (more than 500 ft) that the curvature seems to have had little or no effect on the value of *n*. There is one 8-in. inlet and one 20-in. lateral sewer within the stretch. It is not known whether the 8-in. inlet was discharging any water during the tests, but the 20-in. lateral sewer was discharging a volume equal probably to about 10% of the total volume flowing in Sewer C. However, this lateral is situated so near the upper end of the test reach (71 ft downstream) that the resulting error due to the addition of this flow within the reach should be slight. The entire surface of the sewer is unlined concrete. The concrete of the sidewalls was originally poured against wooden forms and the invert was probably given a troweled finish similar to that given Sewer B.

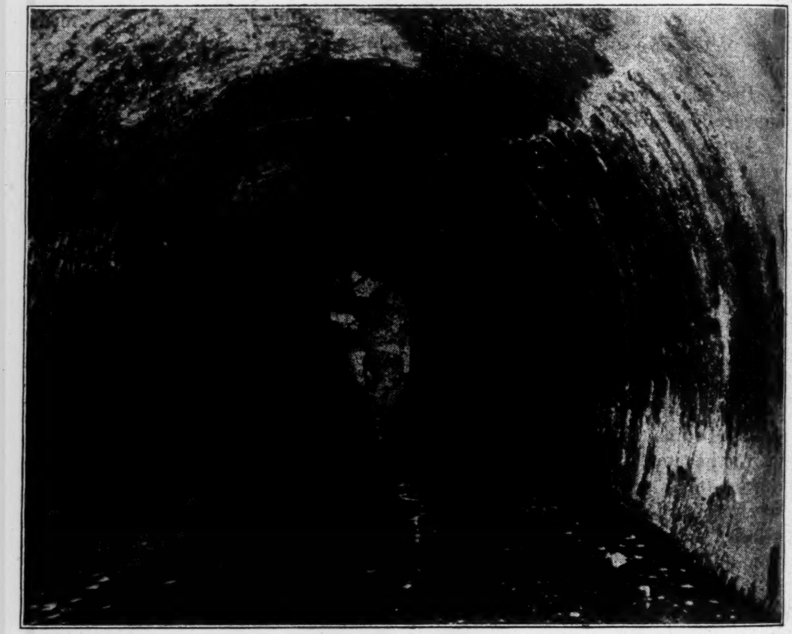

FIG. 5.—A VIEW IN SEWER C, WITH A PORTION OF THE FLOW DIVERTED TEMPORARILY

At the time of the tests the condition of this sewer was good, and the concrete surface fairly smooth (see Fig. 5)—about as smooth as the concrete of Sewer B. An inspection, made with most of the flow temporarily diverted,

[a] "Blue" denotes soluble Prussian blue dye (sodium ferri-ferrocyanide); "salt" denotes sodium chloride; "fluor" denotes fluorescein dye; and "dichr" denotes potassium dichromate. [b] Approximate weight. [c] Dissolving water required. [d] Slope of water surface, S, and mean depth of flow, d. [e] Mean values. [f] Col. 7 ÷ D (in which D = vertical diameter of the sewer). [g] V_c = mean value, centroid vertical; and V_m = mean time of appearance. [h] Based on the mean time of dye appearance for the dye tests, and on the centroid vertical for the salt and dichromate tests. [i] Titration of samples was used for these tests. The electrical-resistance method was used for other salt (and dichromate) tests.

two years prior to the time of making the velocity measurements, revealed that this part of the sewer was in good condition, with the exception of a 50-ft stretch where the arch was severely cracked. The gravel was loose along these cracks, and there were also quite a few transverse hair cracks and a few longitudinal hair cracks for short stretches (as in Fig. 5). The defective conditions would probably have little or no effect on the value of *n* under the conditions of the tests made. During this same inspection two short stretches of deposit, both in the vicinity of the 20-in. lateral, were discovered. One stretch extended 50 ft, averaging about 2 in. deep at the center of the sewer, and the other stretch extended 20 ft, averaging about 1 in. deep. Conditions at the time of the tests were substantially the same as when the inspection was made.

General Results.—Two salt-velocity tests were made in Sewer C by the titration method and two by the electrical method. The results of the electrical determinations are shown graphically in Fig. 6. The principal data and the results of all the tests made in this sewer are given in Table 2(*b*). As in Fig. 3, Points B, P, and E for Test No. C-5 denote, respectively: The beginning of increased chloride content; the peak of the salt content; and the end of the increased chloride content. The line of normal chloride content is marked BE, and M denotes the mean time of salt appearance.

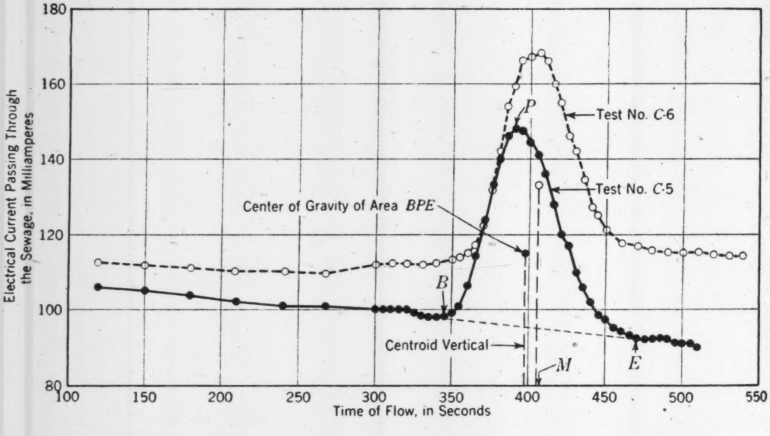

Fig. 6.—Electrical Determinations of Increased Chloride Content in Sewer C

Table 2(*b*) shows that there is a comparatively wide difference between the results of the first series of tests in this sewer, using dye and titration of sewage samples, and the results of the second series, using electrical methods with salt. No particular reason is known for this difference. The two series were made on different dates when there may have been a variation in the lateral sewer discharge or possibly in some other factor not apparent. The accuracy of the

FIG. 7.—A VIEW IN SEWER D, WITH FLOW CONDITIONS SIMILAR TO THOSE DURING VELOCITY MEASUREMENTS

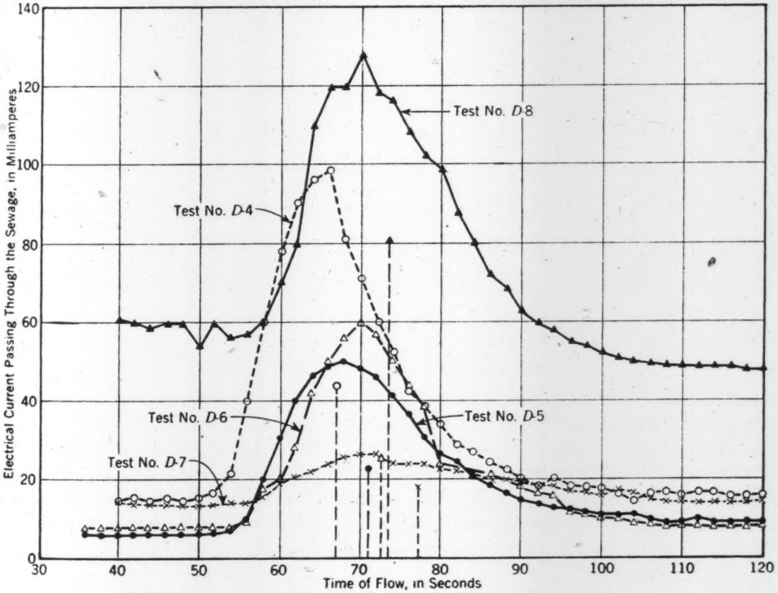

FIG. 8.—ELECTRICAL DETERMINATIONS OF INCREASED CHLORIDE CONTENT IN SEWER D

methods used during the second series certainly exceeded that of the first series; the crew was also considerably more experienced when making the second series. For these reasons the values of *n* determined from the later tests (Nos. C-5 and C-6) appeared the more reliable.

Value of n.—Based on the centroid vertical the average value of Kutter's *n* for Sewer C, at the depths encountered, is 0.0139. However, the value accepted for use in the gaging work is 0.0135, giving more weight to the values determined from Tests Nos. C-5 and C-6—namely, 0.0131 and 0.0135. The value of *n* for this sewer when substantially filled is probably about 0.0130.

SEWER D

Description and Condition of Sewer.—This is the old brick sewer in Third Street, north of Main Street, constructed in 1873. Within the test reach the sewer is straight and on a uniform grade. There was little or no sewage being discharged into the sewer within this stretch while the tests were being made. At the time of the tests the condition of this sewer was good, considering its age (see Fig. 7). In general, the joints were well filled, and there were few pronounced irregularities in the brick surface. The walls were fairly straight—in fact, it was easy to see from manhole to manhole.

General Results.—Electrical methods were used exclusively for the salt tests in this sewer, since, in view of the extremely short time of flow (varying from 67 to 77 sec), it would have been impossible to take sewage samples sufficiently fast to obtain accurate results. As an experiment potassium dichromate was used, successfully, on the last test. The results of these tests are shown graphically in Fig. 8, and the principal data and the results of all the tests made in this sewer are given in Table 2(*c*). The results of the individual tests made in this sewer are fairly consistent in spite of the extremely short time of flow.

TABLE 3.—SUMMARY OF AVER

No.	Kutter's *n*, based on:	SEWER A		
		Dye	Salt	All
1	Peak, dye or salt content	0.0140	0.0137	0.0138
2	Centroid vertical	....	0.0140[a]	0.0140
3	Mean time, dye or salt appearance	0.0146	0.0145	0.0145
4	Discharge of flume	0.0151	0.0148	0.0149
5	Value adopted for gaging work		0.0140	

Value of n.—Based on the centroid vertical the average value of Kutter's *n* for Sewer D, at the depths encountered, is 0.0164. This value was accepted for use. The value of *n* for this sewer when substantially filled is probably about 0.0150.

SUMMARY OF AVERAGE VALUES OF n

The average values of Kutter's n for all the sewers are summarized in Table 3, which indicates that the average value based on the centroid vertical of the salt tests was accepted for the gaging work in every instance except one. The reason for the variation in this instance has been given.

COMPARISON OF KUTTER'S n WITH MANNING'S n

For comparison, the values of Kutter's n based on the centroid vertical of the salt-velocity tests are shown in Table 4 with the corresponding values of n in the Manning formula.[10]

In the case of Sewers B and C, the respective values of n are practically the same. These two sewers had the largest hydraulic radii of the four. There is a small difference in the two values for Sewer A, but the greatest difference is found in the case of Sewer D, for which the hydraulic radius was the least. In the light of similar comparisons previously made,[10] this relation between the values of n in the two formulas is not abnormal.

CONCLUSIONS

1. In general, higher values of n should be used for low flows in sewers than for flows of greater depths. The values given in Table 5, based largely on the tests described herein, are suggested for use in the absence of experimental data indicating other values. The values shown in the table are fairly consistent with such other tests on sewers as have come to the writer's attention, with a few exceptions. However, the values are higher than those found by others for conduits carrying clean water, probably because of the thin coating of slime and grease deposited on the sewer walls by sewage over a period of years.

2. The reasons for higher values of n for low flows are not clear. Friction between the free surface of the water and the air above has been suggested.[3]

TABLE 4.—COMPARISON OF KUTTER'S *n* WITH MANNING'S *n*, BASED ON THE CENTROID VERTICAL OF THE SALT-VELOCITY TESTS

No.	Coefficient *n*	Test Numbers: 3	4	5	6	7	8	Average
				(*a*) Sewer A				
1	Kutter	0.0140	0.0141	0.0140	....	....	....	0.0140
2	Manning	0.0148	0.0145	0.0144	....	....	....	0.0146
				(*b*) Sewer B				
3	Kutter	0.0155	0.0144	0.0139	0.0139	....	....	0.0144
4	Manning	0.0160	0.0146	0.0140	0.0139	....	....	0.0146
				(*c*) Sewer C				
5	Kutter	0.0144	0.0145	0.0131	0.0135	....	....	0.0139
6	Manning	0.0143	0.0144	0.0130	0.0134	....	....	0.0138
				(*d*) Sewer D				
7	Kutter	....	0.0160	0.0166	0.0168	0.0166	0.0159	0.0164
8	Manning	....	0.0194	0.0203	0.0207	0.0206	0.0195	0.0201

The coating of slime and grease on the lower sections of the sewer walls may have some influence.

3. The dye-velocity and the salt-velocity methods can be applied conveniently for measuring velocities of flow in sewers partly filled. The salt-velocity method gives more satisfactory, and probably more accurate, results than the dye-velocity method, and the use of electrical resistance for determining relative salt content is decidedly much easier and quicker than titration of samples.

4. For dye-velocity tests the average time of passage of the dye is indicated best by the average time between the first and last appearance of the dye at the observation point. For salt-velocity tests the average time of passage of the salt is indicated best by the centroid vertical of the area of increased chloride content.

TABLE 5.—SUGGESTED VALUES OF *n* FOR SEWERS HAVING NO OBSTRUCTIONS

Depth of flow (1)	*n*: Minimum (2)	Average[a] (3)	Maximum (4)
	Monolithic-Concrete Sewers		
0 to ⅛ full..........	0.0140	0.0150	0.0160
⅛ to ¼ full..........	0.0135	0.0145	0.0155
¼ to ½ full..........	0.0130	0.0140	0.0150
½ full to full........	0.0125	0.0130	0.0135
	Old Brick Sewers		
0 to ¼ full..........	0.0160	0.0170	0.0180

[a] Recommended values for use where inside surfaces are fairly smooth and otherwise in good condition. Lesser or greater values should be used where conditions warrant.

5. For measuring velocities in sewers partly filled, the samples for titration should not be taken, nor should the electrodes be placed, at the center of the sewer. Additional field tests are desirable to indicate the best point in the cross section for taking the samples and for placing the electrodes.

Conclusion 4 indicates that the use of the average time of passage of the dye may give results approximating those obtained by use of the centroid vertical of the salt tests. This may appear illogical. Indeed, at first glance, the results of the measurements described herein (see Table 3) do not seem to substantiate the conclusion stated. However, recalling that the values of n based on these salt tests are thought to be possibly as much as 2% to 5% low, since only the fast water is timed, the results appear more consistent in this respect. Moreover, when using dye there is little or no alternative to accepting the average time between the first and last appearance of the dye for computing the velocity. There is no other time subject to satisfactory determination, and, indeed, this time is difficult to determine satisfactorily when using the dye in a sewer. However, for the salt tests there is ample evidence supporting the use of the centroid vertical of the area of increased chloride content.

(A possible reason why the average time of the passage of the dye should agree closely with the time indicated by the centroid vertical is advanced by C. M. Allen and E. A. Taylor.[6] This reason is that the eye cannot detect the entire curve of real color but sees only the portion of the curve formed when the dye is not too diluted; that is, portions of the color curve near each end are not detected. As a rule, the average time obtained by observing the visible part of the curve agrees fairly closely with the time obtained by use of the centroid vertical of the salt tests.)

ACKNOWLEDGMENTS

The work described herein was done by the engineers of the Commissioners of Sewerage of Louisville, Ky., under the general direction of the late Woolsey M. Caye, M. Am. Soc. C. E., at that time technical engineer for the commission. Aid and advice were given by the commission's consulting engineers, Metcalf and Eddy, of Boston, Mass. The work was under the immediate direction of the writer, then senior engineer for the commission. On some of the field tests assistance was rendered by Stuart E. Coburn, chemist for Metcalf and Eddy.

DISCUSSION

THOMAS R. CAMP,[11] M. AM. SOC. C. E.—The measured values of velocity and friction factor submitted by Mr. Johnson, for partly filled sewers, constitute a valuable contribution in a field where reliable measurements are very scarce. The data for Sewer A and Sewer D are of general interest because they apply to a circular cross section; and they are especially valuable because the depths are so small.

It has been known for some time (and the author has so stated) that the value of Kutter's n varies with the depth of flow in a sewer. Information on the manner of this variation has been so scarce, however, that it has been necessary in design to assume a constant value of n regardless of the depth of flow. This practice is illustrated in the shapes of the curves for the "hydraulic elements" appearing in most textbooks on sewer design; in which the velocity for a half-full circular pipe is shown to be the same as the velocity for the full pipe (see the broken-line curve in Fig. 9).

In measuring the friction factor in a sewer, the experimenter has no control over the discharge and must accept the flow at the time of the measurements. Therefore, the scarcity of measurements for any substantial variation in depth for the same sewer is quite understandable. In fact there was no substantial variation in depth during Mr. Johnson's measurements, and the conclusion that n varies with depth hardly can be drawn solely from his recorded observations.

It is to be regretted that the opinion is so widely held that measurements made in pipes carrying clean water are not applicable to the flow of sewage. Such is not the case for clean sewers. The amount of suspended matter normally present in sewage is so small that it has a negligible effect on the flow pattern in the pipe. The friction factor is a function only of the Reynolds number and the pipe roughness, and therefore measurements made with clean water are equally applicable to sewage flowing in the same pipe.

Measurements such as those made by Mr. Johnson are of limited value unless the results can be used to predict what the friction factor will be at other depths of flow. His estimates for the values of Kutter's n for the sewers flowing full are not substantiated by any experimental measurements, and they throw no light upon the value of n for other depths.

The best experimental measurements for sewers of circular cross section flowing partly full appear to be those of E. R. Wilcox[12] on 8-in. clay and concrete sewer pipe and S. M. Woodward, Hon. M. Am. Soc. C. E., and the late D. L. Yarnell, M. Am. Soc. C. E.[13] on open-butt-joint concrete and clay drain tile 4 in. to 12 in. in size. In Mr. Wilcox's work the pipes were clean and were laid carefully with good joints. The drain tile used by Messrs. Yarnell and Woodward was placed carefully in earth but with open-butt joints. The depth ranged from about $\frac{1}{4}$ full to full, in these experiments. The results showed conclusively that the friction factor decreases as the depth of flow increases, but the data were so erratic that reliable and accurate trends of friction factor with depth were not apparent.

[13] "The Flow of Water in Drain Tile," by D. L. Yarnell and S. M. Woodward, *Bulletin No. 854*, U. S. D. A., 1920.

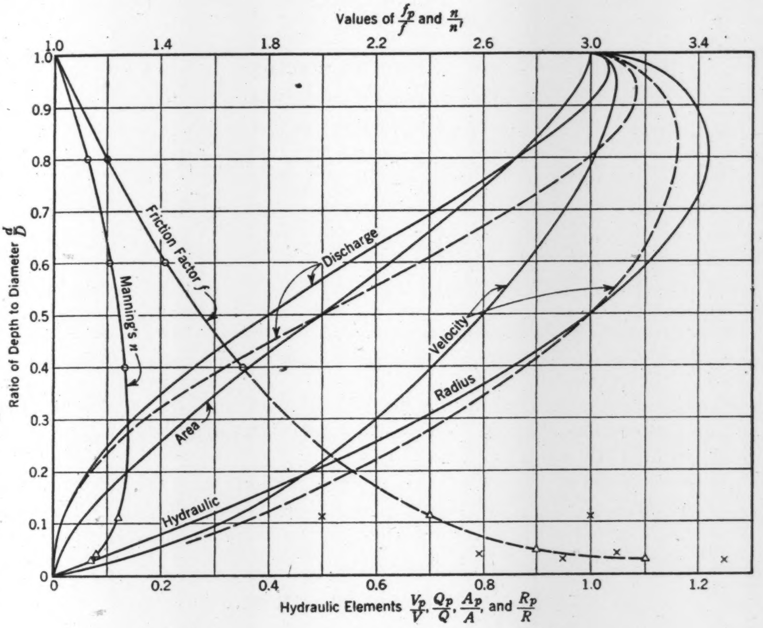

FIG. 9

The writer undertook a study of these data[12, 13] in an effort to find a trend of friction factor with depth.[14] The average value of the Weisbach-Darcy friction factor f in Mr. Wilcox's work was about 0.019 (Manning's $n = 0.0095$) for 8-in. vitrified sewer pipe flowing full and about 0.022 (Manning's $n = 0.0102$) for 8-in. concrete sewer pipe flowing full. In the experiments of Messrs. Yarnell and Woodward, the average values of f and Manning's n for the pipes flowing full were as shown in Table 6. These values are much less than those generally used in practice. (The subscript p herein denotes "partly full.")

A study of the ratios of the values of the friction factor for partly full f_p and full pipes f in these experiments indicates a trend as shown by the points marked with circles in Fig. 9. These points represent the average results of 824 experiments by Messrs. Yarnell and Woodward on well laid drain tile, both concrete and clay. The average values of $\frac{f_p}{f}$ for each pipe size for slopes varying from 0.0005 to 0.015 are shown in Table 6.

---

[14] "Final Report of the Committee to Study Limiting Velocities of Flow in Sewers, March 4, 1942," *Journal*, Boston Soc. of Civ. Engrs., October, 1942, p. 286.

The values of the ratios $\frac{f_p}{f}$ shown from the experiments of Messrs. Yarnell and Woodward as well as from those of Mr. Wilcox were quite scattered; but the averages for each ratio of depth to diameter, $\frac{d}{D}$, checked closely for both studies, the maximum deviation being about 5%. The experimental data seemed to show no consistent influence of the pipe material or of the variation in pipe size or slope. Mr. Wilcox used slopes of 0.005 to 0.04, so that the range of slopes for both sets of data was 80 to 1.

TABLE 6.—RATIOS OF FRICTION FACTORS $\frac{f_p}{f}$ FOR VARIOUS DEPTH-DIAMETER RATIOS

Pipe size (inches)	Friction factor, f	Manning's n	DEPTH RATIOS, d/D		
			0.8	0.6	0.4
4	0.033	0.0111	1.28	1.8	....
5	0.028	0.0106	1.15	1.34	1.9
6	0.027	0.0107	1.22	1.50	1.9
8	0.025	0.0108	1.18	1.38	1.7
10	0.023	0.0108	1.06	1.12	1.32
12	0.021	0.0107	1.21	1.40	1.70
Average	....	....	1.20	1.42	1.70

A study of the effective roughness projection k in these pipes was made from the von Kármán-Nikuradse[15] theory of turbulent flow in full pipes. The value of the friction factor f as given by Theodor von Kármán, M. Am. Soc. C. E., is, for smooth pipe—

$$\frac{1}{\sqrt{f}} = -0.8 + 2 \log (\mathbf{R} \sqrt{f}) \qquad (2a)$$

and, for rough pipe—

$$\frac{1}{\sqrt{f}} = 1.74 + 2 \log \frac{D}{2k} \qquad (2b)$$

in which $\mathbf{R}$ = the Reynolds number $= \frac{V D}{\nu}$ and k = the roughness projection on the pipe wall. The effective roughness projection on the walls of the pipe for the experiments of Messrs. Yarnell and Woodward is about 0.4 mm from Eq. 2b and is somewhat less for the pipe used by Mr. Wilcox.

A fairly good estimate can be made of the values of f for Mr. Johnson's Sewer D, and for Sewer A considered as a circular conduit, by guessing at the effective roughness projection k. From the description and from Fig. 2, a value of 0.5 mm seems reasonable for k, in Sewer A. From Eq. 2b, the corresponding value of f is 0.0117, assuming that turbulence is fully developed in the boundary film. For a smooth pipe, the value of f for Sewer A would be 0.0081 from Eq. 2a. An investigation of the thickness of the laminar film for the smooth pipe indicates that turbulence is not fully developed for k = 0.5 mm.

---

[15] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, McGraw-Hill Book Co., Inc., New York, N. Y., 1938.

Hence a somewhat smaller value of f, say 0.011 (Manning's $n = 0.0125$), is selected for Sewer A. From the photograph of Sewer D (Fig. 7), a value of $\frac{1}{4}$ in. seems reasonable for k; and, since turbulence is fully developed near the wall, the corresponding value of f is 0.038 (Manning's $n = 0.016$).

The writer has computed the values of f, from the author's measurements, and the corresponding ratios $\frac{f_p}{f}$ based on the foregoing values of f. For Sewer A, the average value of f_p for runs 1, 2, 4, and 5 is about 0.031 for $\frac{d}{D} = 0.042$, the corresponding value of $\frac{f_p}{f}$ being 2.8. For Sewer A, if $\frac{d}{D} = 0.028$, f_p is about 0.035, and $\frac{f_p}{f} = 3.2$. For Sewer D, if $\frac{d}{D} = 0.11$, the average value of f_p is about 0.09, and $\frac{f_p}{f} = 2.4$. The points corresponding to these values of $\frac{f_p}{f}$ are shown as triangles in Fig. 9, and the previously constructed curve has been projected through them.

For Sewer D, if the effective roughness projection k is $\frac{1}{2}$ in. or $\frac{1}{8}$ in., the corresponding values of $\frac{f_p}{f}$ are 2.0 and 3.0, respectively. For Sewer A, if f is taken at 0.010 or 0.012, the corresponding ratios $\frac{f_p}{f}$ are 3.1 and 2.6 for $\frac{d}{D} = 0.042$, and 3.5 and 2.9 for $\frac{d}{D} = 0.028$. These points are indicated as × in Fig. 9 for comparison with the selected values.

The effect of the variation of $\frac{f_p}{f}$ as shown by the curve upon the "hydraulic elements" is to displace the velocity and discharge curves from the positions indicated by the broken lines to the positions shown as solid lines.

The values of the ratio of Manning's coefficient,

$$\frac{n_p}{n} = \left(\frac{R_p}{R}\right)^{1/6} \sqrt{\frac{f_p}{f}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

have been computed from the corresponding values of $\frac{f_p}{f}$ and are shown in Fig. 9. The positions of the curves $\frac{f_p}{f}$ and $\frac{n_p}{n}$ in this figure are based upon the best available experimental data, but these data are none too reliable for the purpose. Accurately controlled hydraulic laboratory work for a more precise evaluation of these functions is badly needed.

RICHARD G. COULTER,[16] JUN. AM. SOC. C. E.—In his work at Louisville, Ky., the author encountered a phenomenon reported by earlier investigators. In a given channel, Kutter's n tends to increase as the depth of flow decreases. In his conclusions, Mr. Johnson attributes the higher values of n at low flows to friction between the sewage surface and the air and the coating of slime and grease on the lower section of the sewer walls.

---

[16] Draftsman, C. C. Combs Organization, New York, N. Y.

The results of a very comprehensive series of experiments on drain tile, 4 in. to 12 in. in diameter, with slopes varying from 0.0005 to 0.015 and with depths of flow varying from about one fourth of the diameter to full,[13] were reported by S. M. Woodward, Hon. M. Am. Soc. C. E., and the late D. L. Yarnell, M. Am. Soc. C. E., in 1935. These were laboratory experiments conducted with great care; but the results with flow at part depth varied considerably. They showed, in general, that the value of n was greater when the drain was partly filled than when entirely filled, the excess at one fourth of the depth being roughly from 10% to 50%; but there were a few cases in which lower values of n for less depths of flow were found.

Theodore Horton, M. Am. Soc. C. E., published the result of gagings in the sewers of the North Metropolitan Sewerage System of Massachusetts.[17] In this work n both increases and decreases, with increases in the depth of flow (hydraulic radius). In a description of the sewers gaged it is stated that: Deposits of grease and organic matter appeared on both sides of the channels, greatest near the line of average flow; and there was practically no deposit on the bottom of the channels (probably due to the cleansing action of the sand being swept along).

Mr. Horton's results and description show that the channel condition influences n in operating sewers. The investigations of Messrs. Woodward and Yarnell, however, were on clean pipe in the laboratory. In their work, air friction may have some, but probably only slight, influence on the increasing value of n.

A more basic explanation of the variation in n with change in depth of flow may be obtained by recalling the laws of hydraulics used to derive the Chézy formula, Eq. 1. Fundamentally the resistance to flow is directly proportional to the frictional surface and variable with the velocity of flow in the relation, frictional resistance $= f\,V^y$. In addition, internal resistance in the fluid varying with the viscosity and diameter of the conduit must be taken into account. The effect of the diameter being inversely proportional to power, m, of the diameter.

Thus frictional resistance F, taking into account all the experimentally determined facts, becomes:

$$F = K \frac{V^y}{d^m} \qquad \text{(4)}$$

From this the elemental formula for difference in elevation of the hydraulic gradient (or surface of stream) is derived:

$$h = K \frac{l\,V^y}{d^x} \qquad \text{(5)}$$

in which K = a constant for wall friction; y = the coefficient of velocity relative to wall friction; and x = the coefficient of diameter or hydraulic radius relative to internal friction.

---

[17] "Flow in the Sewers of the North Metropolitan Sewerage System of Massachusetts," by Theodore Horton, *Transactions*, Am. Soc. C. E., Vol. XLVI (December), 1901, p. 78.

To change the form of Eq. 5: $V = \left(\frac{1}{K}\right)^{1/y} d^{x/y} \left(\frac{h}{l}\right)^{1/x}$; $V = K' \, d^{\alpha} \left(\frac{h}{l}\right)^{\beta}$;

or

$$V = C \, R^{\alpha} \, S^{\beta} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

In Eq. 6 the coefficient C is constant for a channel of given material when α and β are assigned correct values. (Formulas giving varying exponents for different classes of channels have been introduced.[18]) By inspection, it will be seen that α and β are influenced by the velocity, friction, and diameter or hydraulic radius.

In the Chézy formula α and β are assumed constant at 0.5. Therefore, C is no longer a constant indicating channel friction; it becomes a variable chiefly influenced by roughness, modified by slope and cross section to compensate for errors in the exponents assigned to R and S.

The empirical Kutter formula, devised to obtain values for C, contains the variables n, R, and S, with n as a constant for roughness and R and S to correct for the conditions of flow. However, R and S have constant exponents when their inclusion is necessitated to correct for exponential variation. The result, when C is determined for various depths of flow in a given channel solving the Kutter formula for n, causes n not only to indicate roughness but also to reflect the changes in hydraulic radius.

C. E. RAMSER,[19] M. AM. SOC. C. E.—Since the paper appears to lack data on the effect of depth of flow on the value of n for tile pipes exceeding 12 in. in diameter, the writer offers the results of experiments on the flow of water in a 30-in. concrete tile pipe line under actual land drainage conditions in Murray County, Minnesota, during 1920.

For slope and current meter measurements, two manholes of 30-in. concrete tile were constructed 1,000 ft apart, the lower manhole being 234.5 ft above the outlet end of the tile line. Elevations of points at the manholes were established from which the elevation of the water surface could be determined by vertical measurements. From these elevations the slope of the water surface was computed, and current meter measurements were made with a rod-type current meter both in the lower manhole and in the ditch about 50 ft below the outlet of the tile. The manholes, consisting of 30-in. tile set up vertically, were built so as to cause practically no interference with the uniform flow of water in the tile. An 8-in. circular hole about in the center of the manhole was cut at a joint in the top of the tile. The manhole tiles were cemented around the bottom and at the joints to prevent leakage when the pipe was flowing under pressure.

The section of pipe where the experiments were conducted was straight and 1,000 ft in length. The tile pipe sections were laid with cemented butt joints along, and for some distance above, this section where a pressure head was expected.

---

[18] "Handbook of Hydraulics," by Horace W. King, 3d Ed., McGraw-Hill Book Co., Inc., New York, N. Y., 1939, pp. 270–271.

[19] Chf., Hydrologic Div., SCS, U. S. Dept. of Agriculture, Washington, D. C.

Inspection at the two manholes indicated that the elevation of the abutting pipes at the joints varied from one half to three fourths of an inch. The tile was clean and free from any kind of growth.

Table 7 contains the results of the experiments. Measurements of the discharge and slope of the hydraulic gradient were made for depths of flow of from 0.67 ft to full with ratios of depth of flow to diameter of tile ranging from 0.27 to 1.00. The depth of flow was taken as the average of the depth at the upper and lower manholes. The area of flow used in the computations was taken as the average of the areas at the upper and lower manholes, which explains the fact that the average depths of flow given in Table 7 do not correspond to the average area of flow. The hydraulic radius was taken as the average of the hydraulic radii at the two manholes.

TABLE 7.—EXPERIMENTS ON THE FLOW OF WATER IN A 30-IN. CONCRETE TILE PIPE LINE

(D = Diameter of Tile; and A = Cross-sectional Area of Tile)

7	1.59	0.64	3.28	0.67	0.713	9.74	2.97	0.001017	110.3	0.0127
8	1.31	0.52	2.60	0.53	0.640	6.56	2.52	0.000966	101.3	0.0135
9	1.21	0.48	2.35	0.48	0.610	4.95	2.11	0.000966	86.9	0.0154
10	0.74	0.29	1.22	0.25	0.420	1.63	1.34	0.000976	66.1	0.0178
11	0.67	0.27	1.06	0.22	0.388	1.31	1.24	0.000966	60.1	0.0186

Measurement No. 1, Table 7(*a*), was made when the pipe was flowing under pressure for the entire length of the slope course, and measurements in Table 7(*b*) were made when the pipe was flowing under pressure at the upper end of the slope course as determined from observations at the manholes at both ends of the course. Measurements in Table 7(*c*) were made when the tile was flowing partly full under no pressure, the average depth of flow ranging from 0.67 ft to 2.26 ft, and the ratio of $\frac{d}{D}$ ranging from 0.27 to 0.90. Attention is called to the rather consistent decrease in value of n in Kutter's formula for an increase in depth of flow. The values obtained for the two smallest depths of flow are slightly higher than the values given by the author for the somewhat smaller depths of flow for the 24-in. brick circular sewer D.

C. Frank Johnson,[20] M. Am. Soc. C. E.—Discussers have added some information on the variation of Kutter's *n* for conduits partly filled. This information relates largely to conduits carrying clean water, rather than to sewers; and to laboratory experiments, rather than to field measurements. As previously stated by the writer, such information affords a valuable guide for use in sewerage computations, but cannot be used without modification.

Professor Camp expresses regret that "the opinion is so widely held that measurements made in pipes carrying clean water are not applicable to the flow of sewage. Such is not the case for clean sewers." The writer is of the opinion that there is no such thing as a "clean sewer," even though there are sewers which are free of deposits and sediment. The nature of sewage is such that the sewer walls are inevitably affected over a period of years after the sewer is put in use, the walls acquiring a surface different from that found in a conduit carrying clean water. This surface condition, rather than the suspended matter in the sewage, is what affects the flow in a sewer. The flow pattern in a sewer would probably be substantially the same for experiments made with clean water flowing in the sewer as for those made with sewage. Professor Camp's study of the ratios of friction factors for various depth-diameter ratios is of considerable interest.

Mr. Coulter mistakenly attributes to the writer the conclusion that higher values of *n* at low flows may result from friction between the sewage surface and the air. This conclusion was merely quoted from another published article. Mr. Coulter's explanation of the variation of *n* is of interest, and the writer has no quarrel with it. However, attention is again directed to the fact that the flow in sewers is affected to some degree by the peculiar condition of the walls, as well as by factors affecting other conduits.

The data contributed by Mr. Ramser are most valuable, ranging as they do from a condition of the conduit being about one fourth filled to completely filled.

In conclusion, the writer urges that additional field measurements be made in sewers partly filled, to supplement the meager information on this subject. Reliance on laboratory and other measurements made in conduits carrying clean water is not entirely satisfactory for sewerage work.

Paper No. 2210

ORGANIZING AND FINANCING SEWAGE TREATMENT PROJECTS

BY SAMUEL A. GREELEY,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. MILTON P. ADAMS, HAL F. SMITH, HERBERT MOORE, FRANCIS H. KINGSBURY, A. BRINTON CARSON, AND SAMUEL A. GREELEY.

SYNOPSIS

The creation of sewage treatment projects is limited, in this paper, to organizations established for the single purpose of sewage treatment and having this limited objective. According to administrative functions, organizations are considered under three classes:

1. Those which function as an arm of the state;
2. Those which function as an arm of a municipal corporation; and
3. Those which are created as new independent, overlapping municipal corporations.

According to geographical character, organizations are considered as local, metropolitan, or regional. The cause, creation, and administration of these special organizations are described with special reference to the Illinois Enabling Act of 1917.

Methods of financing sewage disposal projects are discussed with special reference to revenues from service charges and to loans secured by the revenue. The fundamental considerations in the computation of a charge for sewage disposal service relate to the three principal kinds of sewage for which the service is rendered—sanitary or domestic sewage, storm water, and trade waste. Methods of evaluating these services in terms of a rate of charge and some reference to court decisions and commission rulings are included.

GENERAL STATEMENT

The subject of this paper divides itself into two interrelated parts—organization and financing. These functions are governmental and political. Therefore, trends in the functions are influenced by motives and ideas other

than, and as well as, those of the engineering nature. However, the application of engineering yardsticks and experiences to the results of the organization of sewage treatment projects is useful and enlightening. A great variety of methods for acquiring and financing sewage treatment projects exist throughout the United States. Sanitary districts under the Illinois Enabling Act of 1917 have been successful generally. There has been a trend toward the use of revenue bonds which is likely to continue.

Meanings and Descriptions

The meaning of the word "organization," as used in this paper, requires some description. Citizens may consider that they are organized for the creation of sewage treatment projects when they have become incorporated into a city, town, or village whose charter provides the necessary procedure. Many sewage treatment projects have been undertaken, financed, and operated by this kind of organization. This paper, however, is limited to special organizations created for the one purpose of sewage treatment and having this limited objective. Such special organizations have been created under enabling acts in many of the United States. They differ by having different administrative powers, functions, and procedures, or by being different in geographical character.

In general, special organizations for sewage treatment projects fall into three classes of administrative functions and procedures. One class comprises organizations created to function as an arm of the state. This class remains under the general control of the state; its administrative officers are appointed by the state; its expenditures are so controlled; and it reports to the state. The Metropolitan District Commission of Massachusetts is an organization of this type. A second class is one created as an arm of the city, county, or other municipal corporation. This class functions under the control of an existing municipal corporation and, in general, its administrative officers are appointed by the mayor, or by the municipal governing bodies who also control the expenditures and to whom it reports. The Milwaukee Sewerage Commission is an organization of this type. A third class is one created as a new, independent, overlapping municipal corporation. This class, once it has been created, functions independently of any other local corporations or governing boards. Its administrative officers are either appointed, or elected, but it controls its own expenditures and reports only to the public. Special organizations of this type are The Sanitary District of Chicago, the Minneapolis-Saint Paul Sanitary District, and the Twenty-six Sanitary Districts in Illinois, which have been organized under the Enabling Act of 1917.

The classification of special organizations, in accordance with their geographical character, includes local, metropolitan, and regional districts. Local organizations are those having the same boundary and area as an existing municipal corporation, such as the Buffalo Sewer Authority, the Gary Sanitary District, and the Sanitary District of Indianapolis.

Metropolitan organizations are those comprising a large city, the adjoining municipalities, and, perhaps, some area of unincorporated land. Among these are The Sanitary District of Chicago, the Metropolitan Sewerage Commission of Milwaukee County, and the Minneapolis-Saint Paul Sanitary District.

Regional organizations are those comprising a large area, including a number of municipalities, not necessarily contiguous, and often including a considerable amount of county, township, or unincorporated area. There are relatively few regional organizations for sewage treatment projects. Examples are as follows: North Shore Sanitary District, Illinois, Washington Suburban Sanitary Districts, Maryland, Hampton Roads Sewerage Commission, Virginia, and Passaic Valley Sewerage Commission.

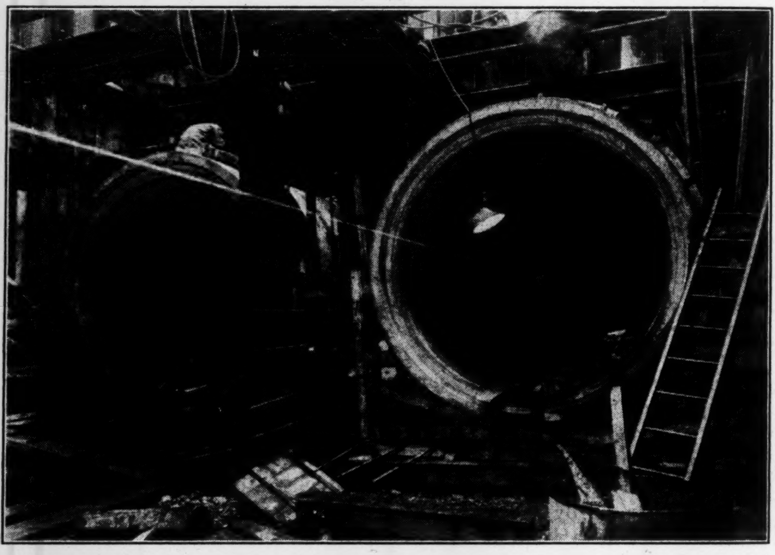

Fig. 1.—Metropolitan Organizations Are Those Comprising a Large City, the Adjoining Municipalities, and, Perhaps, Some Area of Unincorporated Land. The Buffalo (N. Y.) Sewer Authority Is a Metropolitan Organization of This Type. View Shows Construction of Harbor Crossing Which Connects to the Treatment Plant

The foregoing include only the principal kinds of special organizations. In California, for instance, organization is effected through contracts between adjacent municipal corporations. In some cases, special boards or commissions have been created by municipal governments to accomplish a specific sewage treatment project. In 1925, the River Conservancy District Act was passed in Illinois for the special organization of areas co-extensive with the drainage basins of rivers. In general, the trend in the organization of sewage treatment projects has been independent of other local governments.

A major reason for the creation of special organizations has been to secure taxing and financing powers additional to those permitted incorporated municipalities by constitutional restrictions. Thus, under the Illinois Enabling Act of 1917, the sanitary districts have separate powers to issue bonds and levy taxes under the constitutional limitation of the state, in addition to those which can be levied under the constitutional limit by the component cities, towns, and villages. In states with constitutional limitations, special enabling acts cannot give this additional power direct to an existing municipality. Thus, a strong motive behind the creation of special organizations arises from the fact that they permit the undertaking of difficult, highly specialized, and relatively expensive projects. The Illinois 1917 Act provides administration through the appointment, by the county judge, of three trustees who serve for the nominal salary of $300 per year. This permits the responsibility to be centralized on competent and trusted citizens who have no other duties. Thus, if special legislation is required in any event to provide for financing the project, a public desire to secure a special organization also, more or less outside the routine political field, may be fulfilled.

Special organizations have been called sanitary districts, sewerage commissions, authorities, and joint meetings. The term "sanitary district" is used in this paper. Most sanitary districts have power to finance, construct, and operate sewage disposal projects, including intercepting sewers, pumping stations, sewage treatment plants, and appurtenances.

STATUS IN ILLINOIS

Table 1 shows the dates of the enabling acts and of the creation of early sanitary districts. The first one (Item 1, Table 1) is the Boston Main Drainage, which was created by an Act of the Massachusetts General Court in 1876. Acting under authority of the city council, the Mayor of Boston petitioned the Legislature, and obtained the desired authority in an Act to "empower the City of Boston to lay and maintain a main sewer, discharging at Moon Island in Boston Harbor * * *." The second is The Sanitary District of Chicago, Ill., under an enabling act which became law in 1889, the creation of the district taking place the same year. The State of Illinois has had a long and complete experience in the organization of sewage treatment projects. The North Shore Sanitary District (Item 6, Table 1) was organized in 1913, following an Enabling Act of 1911. The first of the Illinois Sanitary Districts under the Enabling Act of 1917 was at Decatur. Thus, since 1889, Chicago and the State of Illinois have had actual experience with the special organization of projects for sewage disposal. Item 5, Table 1, refers to the Passaic (N. J.)

TABLE 1.—DATES OF EARLY SPECIAL ORGANIZATIONS FOR SEWAGE DISPOSAL PROJECTS

Item	Special organization	Enabling act	Creation of district
1	Boston (Mass.) Main Drainage	1876	1876
2	Sanitary District of Chicago, Ill.	1889	1889
3	North Metropolitan Sewerage District (Mass.)	1889	1889
4	South Metropolitan Sewerage District (Mass.)	1899	1899
5	Passaic (N. J.) Valley Sewerage Commission	1902 1907	1902 1910
6	North Shore Sanitary District (Ill.)	1911	1913
7	Decatur, Ill.	1917	1917

Valley Sewerage Commission. The original enabling act of 1902 was declared unconstitutional and the creation of the district was held in abeyance until another act was passed in 1907. The project was finally consummated in 1910. Table 2 lists eleven states in which sanitary districts have been organized. So far as the writer knows, no other states have organized sanitary districts. It should be noted, in the first place, that the record shows sixty sanitary districts in operation in the United States, with a total population of about fourteen million; 46% of the organized sanitary districts by number, and 36% by population, are in Illinois.

TABLE 2.—RECORD OF SPECIAL ORGANIZATIONS FOR SEWAGE DISPOSAL PROJECTS BY STATES

No.	State	Districts (No.)	Population[a]
1	California	1	260,000
2	Illinois	27	4,764,027
3	Indiana	4	623,512
4	Massachusetts	3	1,911,828

8	New York	4	1,654,448
9	Ohio	1[b]	....
10	Wisconsin	4	901,693
11	Virginia	1	270,000[c]
12	Total	58	13,073,030

[a] Approximate population served in 1940. [b] Ten county sewer districts, but no sewer works. [c] 1933 population; the 1941 population was estimated at 450,000.

Table 3 is a brief summary of the progress and present status of sewage disposal in a number of states, in the United States as a whole, and in the State of Illinois. Table 3(*a*) shows the number of sewage treatment plants and the approximate population served in all of the eleven states having sewage treatment projects prior to 1900. There were no sewage treatment plants in any of the other states. In these eleven states there were forty-five sewage treatment plants with an approximate population of 546,000. As of 1940 (Table 3(*b*)), the total estimated population in the United States served by sewage treatment projects has increased to about forty million. The population served in the eleven states which had sewage projects prior to 1900 amounts to nearly

twenty-two million in 1940. Prior to 1900, the population served by sewage treatment plants in Illinois was about 10% of the total so served in the United States, whereas in 1940 it was about 24%.

PART I. ORGANIZATION

Special organizations for sewage treatment projects usually have been created because of the magnitude and difficulty of the project and the need for special financing. Civic leaders have been prompted either to initiate an enabling act, or to lead the community to avail itself of existing legislation. Therefore, sanitary districts are organized to obtain funds beyond the statutory limitations of the municipality or component municipalities, and, in many cases, to provide for a continuing qualified personnel to administer and accomplish the project.

Initiation and Creation

In a general way, sanitary districts are created by enabling acts of the state legislative bodies. Such enabling acts are either mandatory or permissive. Those which are mandatory bring the district into existence with the enabling act, or following the appointment of trustees or commissioners. All of the Illinois Acts are permissive. The area to be organized must petition for an election to determine the question of organizing a district. This step, of course, takes careful account of the rights and prerogatives of the small or local municipality and insures that the state does not usurp any of the local rights.

A recently created sanitation district, known as the Hampton Roads Sanitation Commission, in Virginia, is a regional organization. It was created by an enabling act which provided for an election to determine the question of establishing the Commission. Upon a favorable election, the Commission came into existence when the Governor appointed the five Commissioners provided by the Act. However, the local interests were still further protected by a provision in the enabling act which permits any individual municipality within the sanitary district to declare its intention of withdrawing within six months after the creation of the Commission. Such municipalities as declare their intention to withdraw must, within the next following six-month period, show to the satisfaction of the State Board of Health and the Commission that they have taken the necessary steps to finance, construct, and operate an acceptable sewage disposal project. During these two six-month periods, the Commission cannot take steps to issue bonds. Thus, in addition to the right to vote on the creation of a sanitary district, the local communities are afforded an opportunity to decide whether they will proceed by themselves, or jointly within the sanitary district.

The trend is to continue to safeguard the rights, powers, and interests of the local municipalities.

Area To Be Included

The boundary of the area to be organized is generally included in the originating petition and fixed by the court or other public body hearing and reviewing the petition. In some cases the boundary lines have been fixed by considerations of expediency, such as municipal corporation limits, property lines, and the like. Some enabling acts require a competent preliminary engineering investigation and report, the purpose of which is to assist the reviewing body in determining the area to be included. There is no such requirement in Illinois, but the trend seems to be to give more consideration to the preliminary aspects of organization. When the boundary of a sanitary district has been fixed and bonds issued and money used for permanent construction, it is difficult to diminish the area of the district. It is easier to annex than to disannex. Amendments have been made to existing Acts, providing for annexation or disannexation.

Administrative Board or Commission

In Illinois, the administrative board is elected in the case of The Sanitary District of Chicago, and is appointed by the county judge in all of the other districts. The principal question is the relative merit of election. The size of the district and of the project is likely to have some bearing, but the trend seems to be toward the appointment of the board. The Hampton Roads Sanitation Commission is composed of five members appointed by the governor. The Buffalo (N. Y.) Sewer Authority, one of the recent large special organizations, comprises five members appointed by the mayor.

Another question of interest relates to the compensation of members of the administrative board. In general, this compensation has been nominal. The Sanitary District of Chicago has nine Trustees, three of whom are elected every two years for a six-year term. This is a very large complex undertaking and requires considerable time by the Trustees. Therefore, they are compensated on a relatively liberal basis. In the other sanitary districts in Illinois, each Trustee now receives $300 per year. The members of the Buffalo Sewer Authority receive no compensation. The Chairman of the Hampton Roads Sanitation Commission, who is designated as a "full time member," may receive not more than $6,000 per year. The other members receive a small compensation for attendance at meetings, not to exceed $300 in any one year. The trend is toward a relatively small compensation.

Methods of Financing

The sanitary districts in Illinois are empowered to levy and collect taxes and to issue bonds upon favorable vote by the people. Amendments to the 1917 Act and others provide that the district may apportion and collect an additional charge for the disposal of industrial sewage and may also levy special assessments upon benefited property for the construction of collecting sewers. None of the districts in Illinois can establish and collect charges for sewage disposal service. The Buffalo Sewer Authority and the Hampton Roads Sanitation Commission are authorized to issue revenue bonds and, in fact, are limited to this method of raising money. The trend is to consider a sewage disposal project as a utility, to be operated on a revenue basis.

The Illinois sanitary districts are empowered to levy and collect taxes as soon as they are organized. Although considerable time may elapse before tax money comes in, it is possible for the board to issue tax anticipation warrants, or to borrow moderate sums for administrative expenses. In this way, much-needed engineering and legal services can be engaged promptly. The Hampton Roads Sanitation Commission is limited in this regard by the provision that the appropriation made by the state, except in the amount of $10,000, is not available to them before they are empowered, by an election, to issue bonds. The Buffalo Sewer Authority had no means of securing funds until they issued and sold revenue bonds, the first money being advanced by the Public Works Authority (PWA). Fortunately, however, they were able to use facilities provided by the city. Administrative boards should not be so limited in their early available funds as to handicap the progress of completing the project for which they were created.

Powers

The powers granted sanitary districts are not unusual and are more or less similar throughout the United States. The district is given power to engage engineers, lawyers, accountants, and clerks, to build and operate structures, to acquire right-of-way and property, to make contracts, and to formulate and enforce rules and regulations for the operation of the project. A special power, recently granted, is that of receiving and using grants from the federal government. Many enabling acts permit the district to contract with other districts or municipalities for sewage disposal.

Rules and Regulations

Enabling acts, in general, permit sanitary districts to adopt rules and regulations for the use of the facilities which they provide, but do not ordinarily give them police powers. This is understood to be true as regards The Sanitary District of Chicago. The police power rests with the state. The extent to which sanitary districts can regulate the use of their works has not been thoroughly tested, but, in general, the soundness of the rules and regulations has led to their acceptance by the public. The importance of such rules and regulations and their effect is obvious; for instance, it is important that sanitary districts have control over the construction of new sewers which, in turn, will require sewage disposal service.

General Trend

In recent years few sanitary districts have been organized for sewage disposal projects. In Illinois, the most recent important sanitary district was that at Danville in 1934. Since that time, only three small districts have been organized. Throughout the United States, there are relatively few new organizations, the most recent being the Hampton Roads Sanitation Commission, created in 1941, and, among large projects, the Buffalo Sewer Authority created in 1935. Two reasons are (1) the availability of federal grants and (2) the powers given to municipalities to issue revenue bonds. The experience in Illinois in the administration of sanitary districts under the 1917 Act has been so good that this method of procedure could well be extended to other parts of the United States.

Special Considerations

The creation and organization of sanitary districts in the various states and within each state vary in detail. A few illustrations are pertinent, as follows:

(*a*) The Passaic Valley Sewerage Commission is authorized to formulate projects, but cannot begin to create them until a prescribed number of municipalities within the district have approved the undertakings and obligated themselves to furnish the necessary funds.

(*b*) The East Bay Municipal Utilities District, in California, may purchase or construct only revenue-producing utilities. It cannot purchase or construct such utilities until their acquisition has been first approved by a majority of the voters of the district.

(*c*) The Washington (D. C.) Suburban Sanitary Commission may construct and maintain sewage disposal projects, as well as other utilities, and may extend them into adjacent territory outside of the district, wherever the property owners agree to such an extension. It may make and enforce plumbing regulations and build sewer connections directly to houses. It is empowered to borrow money and to levy a tax or to make special assessments and service charges. Appeals from assessments and service charges can be taken to the Maryland Public Service Commission.

An outline of the items included in the Illinois Enabling Act of 1917 is given in the Appendix.

PART II. FINANCING

The following methods of financing have been used by special organizations for sewage disposal projects:

(*a*) Taxes and borrowings through general obligation bonds;
(*b*) Funds contributed by constituent municipalities within the district;
(*c*) Special assessments on benefited property;
(*d*) Appropriations by the state;
(*e*) Voluntary contributions; and
(*f*) Revenues from service charges and loans secured by the revenues.

As the trend in financing has been toward service charges and revenue bonds, the discussion in this part of the paper will be limited to that method.

History of Revenue Bonds

The use of revenue bonds and charges for sewage disposal service is not new, having been resorted to as early as 1890. However, there are relatively few court decisions and rulings by regulatory commissions. From the viewpoint of general theory and the computation of rate structures, the application to sewage disposal projects is relatively undeveloped. There is need for a broad review of experience, and a development and presentation of procedures for review by courts and commissions. Among the early rate structures are those at Brockton, Mass., and Spokane, Wash., which were established between 1890 and 1900. The Brockton project is still financed by the collection of sewage disposal charges and is a good illustration of a sound rate structure. A survey of the United States made toward the end of 1938 indicated that more than 600 municipalities in thirty-five states were using revenue bonds and the income from sewage disposal charges for financing such projects. There is some confusion in reporting, classifying, and comparing these revenues. In some cases, the rates are sufficient to produce a revenue to meet operating expenses only, and in such cases the debt service is paid by taxes from the general fund. In other cases, the rates are sufficient to produce revenues sufficient for the entire annual cost of the project, including operation and debt service and, in some cases, a reserve or revolving fund for current extensions and replacements. Whenever rates are compared, the items covered by the annual revenue should be stated.

The power of municipalities to establish sewage disposal charges comes from special enabling acts or from sections in acts for establishing special organizations. The various acts grant different powers as to the amount and use of revenue. For instance, the Ohio law includes the following provision:

> The municipality may establish charges and equitable rates or charges of rents to be paid by those whose premises are sewered by a connection to the sewage disposal works, and these charges constitute a lien upon the property sewered by such a connection. The revenue shall be used for the payment of the cost of management, maintenance, operation and repair of the project, and any surplus in such fund may be used for enlarging or replacing parts of the project and for the creation of a sinking fund for the payment of any debt incurred for the construction; it shall not be used for the expansion of the system into unsewered areas.

Other acts provide that the revenues may be used not only for the expenses of operation and maintenance, but also to meet the debt service and to provide a reserve for improvements.

The use of revenue bonds received a considerable impetus from the grants donated to municipalities by PWA. During its active life, PWA aided in the construction of 1,524 sewage disposal projects, of which 230 were financed by revenue bonds. A brief summary of the sums involved follows:

Source of fund	
PWA loans, 22%	$101,500,000
Grants, 37%	171,500,000
Non-federal, 41%	189,000,000
Total	$462,000,000
Loans secured by revenue bonds	
PWA, 26%	$ 26,400,000
Non-federal, 14%	26,500,000
Total	$ 52,900,000

It is of interest to note that about 104 municipalities in Canada are reported as having established sewage disposal charges. It is reported that some 200 municipalities in Texas receive sewage disposal service from projects financed by revenue bonds, and there are a number in Massachusetts and New Jersey.

About 26 municipalities in Illinois have financed sewage disposal projects by revenue bonds and service charges.

DISCUSSION OF TERMS

The term "sewage disposal project" is used in a broad sense to include all degrees of sewage treatment, all of the structures included in the project, as it may have been financed, and, in some cases, the construction of sewers only. In short, it is a comprehensive term describing projects in the field of sewerage and sewage treatment which have been financed by revenue bonds. In some cases, the charges are referred to as sewer rentals[2] or sewer service charges. In the writer's opinion, the term "sewage disposal charge" is the better term.

FUNDAMENTAL CONSIDERATIONS

In general, there are three principal kinds of sewage for which service is rendered, as follows:

Sanitary or domestic sewage;
Storm water (usually comprising the first part of the runoff); and
Industrial sewage or trade waste.

The structures to provide the service will include combined sewers or separate sewers, and the service charge may be limited to a sewage disposal project for sanitary or domestic sewage only, or for combined sewage. This is an important fundamental consideration. In some cases, industrial sewage may be excluded, but, in general, much industrial sewage is discharged into the system. Thus, in considering revenues and rates, the kind of a sewage disposal project must be stated. On this basis, the elements of use or service are the following:

(*a*) Treatment and disposal of sanitary or domestic sewage;
(*b*) Handling and disposal of storm water; and
(*c*) Treatment and disposal of industrial sewage.

The collection of these kinds of sewage may or may not be part of the project, but a consideration and comparison of rate schedules should take the element of service and its cost into consideration. In addition to the foregoing, the municipality must make some provision for future growth and future population, and this is an element of service. Assuming that these are the proper elements of use or service, an effort should be made to measure them and to evaluate or price the quantity of the service. A quite general practice is to consider that sanitary or domestic sewage is reasonably measured by the quantity or use of water in the dwelling, exclusive, perhaps, of water used for lawn sprinkling, and discharged to the sewage disposal project.

Industrial sewages may affect the cost of providing sewage disposal service by their relatively greater strength, as compared with domestic sewage. They may have a relatively high oxygen demand or chlorine demand; they may contain large quantities of suspended solids and grease, difficult to handle;

---

[2] See "Sewer Rental Laws and Procedure," Third Progress Report of the Committee of the Sanitary Eng. Div., *Proceedings*, Am. Soc. C. E., November, 1942, p. 1585.

or they may be discharged in batches, and not uniformly, throughout the 24 hours. Some industrial sewages may contain toxic or corrosive substances. Unless these additional elements of service and their cost are covered in the rate structure, it is possible that a charge of discrimination could be supported on behalf of the domestic user. Fortunately, however, in many municipalities the amount of such annual cost and revenue is not a large proportion of the total, and adjustments can frequently be made by special rates or agreements with industries, in some cases providing pretreatment or equalization structures at the industry.

If the collecting sewers are combined, some (and occasionally much) of the storm water reaches the sewage disposal project. Capacity and treatment for this storm water must be provided and a part of the total annual cost is thus required for storm-water disposal. This service is more a function of the tributary area than of the use of water. Properties of greater area will shed a larger quantity of storm water to the sewers and require a greater sewer capacity, and to this extent a higher cost for disposal. Properties having more impervious surface than others will discharge relatively greater quantities of storm water; and properties of value, where interruptions to their use are costly, require a more extensive and expensive service. Thus, area is indicated as a possible yardstick for measuring this service. The evaluation of this yardstick, in terms of a sewage disposal charge or rate, so far has been computed from the assessed valuation, which gives some weight to the extent, area, and use value of the property. Based on present experience, a charge, on the basis of area and value, appears to be reasonable and expedient.

A fundamental consideration of service is to provide future capacity for the growth and development of the city. Such additional expenditures and annual costs are made for the benefit and use of presently vacant property and for an increased development and use of presently occupied property. Property, therefore, is served by the sewage disposal project. Its use and value are protected and stabilized. This element of service may also be related to area, perhaps through the assessed valuation.

Thus, for combined systems in which the financial structure covers both storm and sanitary sewers, a two-part rate is indicated. One part of the rate might be based on the use of water and the other part on the assessed valuation of property within the area served, or to be served, by the project. Such a two-part rate has been in use at Buffalo for more than three years and has recently been under review by the courts in the case of Philadelphia. Further, to accomplish a reasonable and equitable rate structure, the ordinance should provide for special charges, agreements, or considerations as regards industrial sewages.

COURT DECISIONS

The writer is not aware of many court decisions related specifically to sewage disposal projects. An early one is that of Carson versus Brockton Sewerage Commission, decided by the Supreme Judicial Court of Massachusetts on May 27, 1901. The principal contention of the petitioner was that, having paid an assessment for the installation of the sewers, he could not be forced to pay a special annual rental charge. The Court decided in favor of the City, on the basis that a sewer rental, computed on the quantity of water or the amount of the water bill, was not unreasonable. The Brockton revenue for sewage disposal service is in part a usage and in part a tax levy. The use charge brings in about 60% of the total annual revenue.

In 1942, there was a decision by the Court of Appeals of Richland County, Ohio, in connection with Gatton versus City of Mansfield. The appellant sought relief from the City for shutting off water furnished to her premises, because of her delinquency in payment of sewer rentals. The Court sustained the City. Recently, the Supreme Court of Pennsylvania has considered the case of a proposed sewer rental ordinance for Philadelphia, which establishes a two-part rate, comprising three mills for each dollar of the fair value of the property served, and an amount equal to one-quarter of the water rent. A very complete argument was prepared by the city solicitor, which included references and quotations from many pertinent court decisions, a few of which relate quite directly to sewage disposal service of one kind or another.

COMMISSION RULINGS

There are a number of sewage disposal utilities in the United States which are owned and operated privately, most of them being in New Jersey and in Texas. The New Jersey Board of Public Utility Commissioners has ruled on charges established by some of these private companies, as, for instance, the Lakewood Water Company. The rate approved by the Commissioners comprised a service charge related to the size of the water meter, a consumption charge related to the use of water, and a minimum charge. The service rendered is understood to have been mainly for domestic sewage and not for storm water.

TYPES OF RATE SCHEDULES

There are many types of rate schedules for sewage disposal service,[2] among which are the following:

(*a*) A charge related to the water bill, which may be a percentage of the water bill or may be a separate graduated or uniform scale, related to the quantity of water.

(*b*) A flat rate per connection, according to the class or kind of property.

(*c*) A charge based on the number and kind of fixtures connected to the project.

The kind of rate structure best suited to any community depends upon its size and complexity, whether the services are for sanitary or combined sewage, the number of water meters installed, the amount of revenue to be realized, and what it covers, and other local factors. The trend seems to be toward rates or charges related to the water consumption, with consideration being given to a two-part rate, where this is feasible and appropriate, under the Enabling Act, to local conditions.

EXPERIENCE WITH SERVICE CHARGES

A good indication of the feasibility of financing revenue bonds by sewage disposal charges is the relation between the cash collected and the total amount of the individual bills. Experience in the percentage of collections appears to have been favorable. Table 4(*a*) is taken from the annual reports of Lima, Ohio (population in 1940—44,711).

Experience at Battle Creek, Mich., indicates that current arrears do not, in general, exceed 5% of the bills. In 1936, the bills totaled $52,821, and the arrears $4,459, or 8.4%.

The experience at Buffalo has also been satisfactory. The sewage disposal charges were established to realize a total annual revenue of $1,500,000. The book record of revenue for the three fiscal years of operation is as shown in Table 4(*b*). The actual cash collections have been in excess of 93% of the current bills. Some proportion of the arrears has been in deferred payments by adjacent tributary municipalities, with whom contract adjustments were pending. The general experience with the administration of sewage disposal charges has been satisfactory. There seems also to have been a steady demand for revenue bonds so financed, at reasonable interest rates—generally below 4%.

TABLE 4.—EXPERIENCE AS TO THE PERCENTAGE OF SEWER RENTALS BILLED ACTUALLY COLLECTED

Year	Total billed (dollars)	TOTAL RECEIVED	
		Dollars	%
(*a*) LIMA, OHIO			
1932[a]	27,982.15	26,488.42	94.7
1933	49,054.50	46,244.71	94.3

[a] Nine-month period. [b] Year ending June 30.

GENERAL SUMMARY

There has been a marked trend toward the use of revenue bonds and charges for financing sewage disposal projects. Experience in selling revenue bonds and collecting revenue has been satisfactory. It seems likely that this method of financing will continue and expand. There is need for a further clarification of the structure of rate schedules for sewage disposal service and a classification of present experience in the light of fundamental considerations.

APPENDIX

ILLINOIS SANITARY DISTRICT LAW, ACT OF 1917
AS AMENDED 1919, 1923, 1927

The subjects of various sections, and brief comments on "An Act to Create Sanitary Districts and to Provide for sewage disposal," are as follows:

1. (As amended 1927.) Any area of contiguous territory containing one or more incorporated cities, towns, etc., which can construct and maintain treatment plants, may be incorporated as a sanitary district under this Act in the manner following:

(*a*) Petition to county judge by 100 legal voters to submit to legal voters question of whether territory shall be organized into sanitary district;
(*b*) County judge will then call two judges of the circuit court, and the three shall constitute a board of commissioners to consider boundaries;
(*c*) A 20-day notice of a meeting of Commissioners shall be published;
(*d*) After a meeting and hearing, the Commissioners fix boundaries; and
(*e*) Finally, the case is decided by an election within 60 days after step 1(*d*).

2. Courts must then take judicial notice of the existence of the sanitary district.

3. A board of trustees, consisting of three members, for the management, control, and government of the affairs and business of each sanitary district organized under this Act, shall be created in the following manner:

(*a*) The county judge will appoint trustees, who must be residents of the district. Not more than two shall be appointed from one incorporated town, village, etc., and for terms of 1, 2, and 3 years.
(*b*) (As added in 1919.) The county judge is given power to fill any vacancy.

4. (As amended in 1927.) The powers of the board are to manage and control all the affairs and the property of the district.

5. Ordinances.

6. Proof of ordinances.

7. (As amended in 1927.)

(*a*) The Board has power to provide for the collection and disposal of sewage and drainage, to maintain conduits, pipes, pumps, to contract with other sanitary districts, and to treat and purify sewage—"provided, nothing herein contained empowers the board to operate a system of water works for the purpose of furnishing or delivering water to any municipality or the inhabitants thereof." The Board is not authorized to flow sewage into Lake Michigan.
(*b*) Its duty is to provide sewers and treatment plant; a penalty is provided for violation.
(*c*) It may collect, from producers of industrial waste, the costs of fair additional construction, maintenance, and operating expense, over and above those covered by normal taxes.

8. It may acquire real or personal property by purchase, condemnation or otherwise, etc.

9. It may borrow, issue bonds, etc., but not to exceed 5% on the valuation of taxable property. The question must be submitted to a vote at an election.

10. It may impose a tax to pay indebtedness.

11. Contracts must be let to lowest responsible bidders.

12. (As amended in 1927.) The Board may levy additional taxes after an election has been held to authorize such levy; the tax can be terminated by a later election. The 1927 amendment provides for the certification and collection of taxes, the deposit of funds, etc.

13. Sewers, channels, etc., may cross public property, with the approval of the governor.

14. The Board may contract for sewage from a U. S. military post within its bounds.

15. Condemnation of private property.

16. Condemnation of property held for public use.

17. Power to permit outside territory to use its drains, etc.

18. (As amended in 1919.) Power to prevent pollution of water supply.

19. (As added in 1923.) Power to construct drains, sewers, pumping stations.

20. (As added in 1923.) Special assessments—annual installments.

21. (As added in 1923.) Bonds to anticipate collection of assessments.

22. (As added in 1923.) Cost of acquiring private property to be included in assessment, according to state local amendment act.

23. (As added in 1927.) Additional contiguous territory may be added to any sanitary district organized under this Act, as follows:

(*a*) Petition by 10% of the legal voters of the addition to submit to legal voters of addition such proposal, taxpayers thereof to assume proportionate share of bonded indebtedness, provided no territory disqualified in Section 1 of this Act is included.

(*b*) County judge to call all the county judges in the sanitary district and proposed addition, which body shall constitute a board of commissioners to have power and authority to consider boundaries.

(*c*) Notice of and hearing as provided in Section 1 of this Act.

(*d*) Trustees of district to accept by ordinance annexing the additional territory.

24. (As added in 1927.) Any contiguous territory within boundaries of district may become disconnected from such district in the following manner: Petition by 10% of legal voters of territory seeking disconnection to submit question to legal voters. County judges form commission. Such territory must have no bonded indebtedness incurred while it was a part of the district which has not been paid up, nor any special assessments. Notices and hearings are practically the same as in Section 1 of this Act.

DISCUSSION

Milton P. Adams,[3] M. Am. Soc. C. E.—In the "Synopsis" of this paper, Mr. Greeley limits the scope to "organizations established for the single purpose of sewage treatment and having this limited objective." The writer, in turn, since there are no such organizations in Michigan, must limit his discussion to a listing of the causes underlying the failure to achieve true metropolitan district financing and administration of the sewage treatment function in the area around Detroit. He will also mention briefly some of the problems that have been encountered elsewhere in the State of Michigan in order that the larger community may provide sewage collection and treatment to its smaller neighbor.

An amendment (Art. VIII, Sec. 31) to the State Constitution of Michigan, together with Act 312, Public Acts of 1929, as amended by Act 56, Public Acts of 1935, provides the legal foundation "for the incorporation of any two or more cities, villages or townships or parts of same" into metropolitan districts. Sewage treatment is but one of several objectives attainable through such organization. An intermediate but necessary step to the formation of such a district is the appointment and organization of a charter commission. Rules for selecting representatives on such commission are provided by the enabling statute. Instead of representation being based on outstanding local and nonpartisan qualification for such service, as under the Illinois Sanitary District law, unfortunately, in Michigan, one representative must come from each unit of government irrespective of size, whereas large cities are entitled to only one representative for each 200,000 population, over and above the first 200,000 of population, for which four representatives are allowed.

The charter subsequently must receive a favorable vote from each governmental unit. It is thereafter the magna charta of future administration, financing, and operation of the function sought.

Before sewage treatment was actually under way in Detroit as a city project, Wayne County administration of this service was seriously proposed and reported upon, both as a county drain commissioner's function and as that of the board of supervisors.

A regional committee on sewage collection and treatment, headed by the Hon. William A. Comstock, Governor of Michigan (1933–1934), was organized in 1933. Its objective was the solution of the problems not only of Wayne County's municipalities along the Detroit River but those of southern Oakland and Macomb counties as well. The latter counties border Wayne County on the north.

The following factors appear to account for the failure to achieve a separate and independent regional organization for sewage treatment in the metropolitan area:

1. The predominating size and political relation of Detroit with reference to some forty surrounding or neighboring municipalities of Wayne, Oakland and Macomb counties;

---

[3] Executive Secy.-Engr., Michigan Stream Control Comm., Lansing, Mich.

2. The statute provision, previously mentioned, in which one city with more than 85% of the tributary population and taxable property in the area would have been unable to exercise a controlling voice in the drawing of a charter necessary to the creation of such a district;

3. The situation created in 1935 when, with two applications before it—one by the City of Detroit, and one for Wayne County including Detroit—the PWA chose to deal with Detroit, leaving, for a subsequently submitted Wayne County application, the solution of the problems of the remaining municipalities not served by the Detroit project; and

4. The curb on metropolitan district powers of taxation and bonding inherent in the so-called 15-mill amendment to the State Constitution which became effective in 1933.

The nearest approach to regional administration of sewage treatment in Michigan is now operative under the provisions of Act 342, Public Acts of 1939, as amended by Act 353, Public Acts of 1941, in behalf of those communities in Wayne County not served by the Detroit project. During the spring and summer of 1942, under the stress of the war emergency and further conditioned upon favorable federal action as to the financing of certain necessary capital improvements, Wayne County has become the agent to serve the Grosse Pointe communities along Lake St. Clair as well as certain southern Macomb County municipalities. The treatment of all sewage so collected is by the City of Detroit acting under contract with Wayne County. A Sewage Disposal Committee of the Wayne County Board of Supervisors administers this function through its Board of County Road Commissioners.

Since October, 1939, Wayne County sewage treatment service has been available to its customer municipalities and townships at a uniform base rate independent of location. Until July 1, 1941, the basis of charge was $26 per million gallons of sewage, as measured by water passing the user's water meter. The current rate is $43 per million gallons, less discount, intended to be sufficient compensation to the customer governmental unit for collection of local service charges. The county's contract, therefore, is with the municipal subdivision served and not with the individual user.

The Detroit sewage treatment plant is now operated by the Detroit Water Board. The City Department of Public Works, on the other hand, is responsible for sewer maintenance and controls both city and out-of-city connections to the sewer system.

Only within the past year (1941) has the Common Council of Detroit adopted a so-called metropolitan rate for out-of-city and out-of-county sewage treatment service. To this rate, however, the City Department of Public Works seeks reimbursement as well for flowage or trunkage rights through that portion of its system not provided with PWA assistance. Distantly located municipalities find themselves at a financial disadvantage, therefore, as compared with those located more closely to the city's single sewage treatment plant.

During the summer of 1942, under authority of the county sewage disposal law, the City of Detroit and County of Oakland have reached an understanding whereby the sewage of several southern Oakland County municipalities will be received and treated by the City of Detroit. At the November 3, 1942, election, the municipalities of Ferndale, Royal Oak, Hazel Park, Huntington Woods, Berkley, Pleasant Ridge, and Clawson voted to so amend their respective charters as to enter contracts with the County of Oakland for treatment of their sewage on the county plan.

No privately owned sewage treatment utilities exist in Michigan, although Act 320, P. A. 1927, as amended, provides for their creation and control. Attempts were made to organize sanitary districts at Traverse City, Owosso, and Monroe during 1928–1930 without success. Failure of these efforts is charged to the 8% to 10% return then asked on the necessary capital outlay plus operating charges. Perhaps, reluctance on the part of Michigan communities to encourage additional types of privately owned, public utilities was also a factor.

Among the problems encountered under contract relation between governmental units for sewage treatment service, where well-conducted sanitary district organizations are lacking, are the following:

1. Reluctance to enter into the initial agreement because of uncertainty as to future year-to-year costs;
2. The governmental unit desiring accommodation may be asked to pay any amount in excess of the pro-rata service cost up to such amount as the "traffic will bear" at the will of the party providing the service;
3. The shifting legal responsibility for pollution where shut off or by-passing takes place, in an effort to enforce payment or obtain concessions as to charges; and
4. The Grand Rapids-East Grand Rapids problem of continuity of service to the latter municipality and compensation to the former was assured by a county circuit court hearing and signing by the judge of a contract mutually agreed upon in advance by representatives of the two cities. This contract has a "reopening clause" which has never been invoked since the original agreement was made early in the 1930's. The friendly suit or court hearing attested to by the county judge apparently has overcome the charter limitations of the municipalities which prevents their so contracting as to bind future legislative bodies of the two cities.

Hal F. Smith,[4] **Esq.**—A scholarly presentation of data concerning the development of organization and finance methods for sewage disposal projects is offered by Mr. Greeley. The paper includes a carefully considered description of the trend that the course of development is following. The writer's opinions, which are based entirely on personal experience in the field, are in accord with the author's findings.

The City of Detroit, Mich., made use of its regular municipal organization for construction and operation of its sewage disposal system, and assigned to its Department of Public Works, which includes the office of the city engineer, the task of constructing the system, which consists of intercepting sewers, sewage treatment plant, effluent conduit to the river, and its appurtenances. After completion, the operation of the system, including billing and collecting for service rendered, was transferred to the Department of Water Supply. The regular municipal organization was used because Detroit believes that, in general, economies in operation of municipal departments or projects lie in the path of consolidation of existing agencies rather than in the creation of new agencies.

---

[4] Senior Administrative Asst., Detroit Dept. of Water Supply, Detroit, Mich.

The City had little choice in the matter of financing its sewage disposal project. It had already reached its bonding limit and did not have sufficient cash resources to finance the project; so it decided to use the city funds that were available, accept the PWA grant, and issue revenue bonds to finance the remainder. The revenue bonds were issued by authority of a city ordinance, supported by a state enabling act, which also provided for raising funds to meet the system's debt charges and operating expense by imposing a sewage disposal charge upon the users of the system. It was decided to base the sewage disposal charge on metered water consumption because it appeared that water consumption was the most satisfactory and equitable measure of the service rendered by the sewage disposal system.

Its rate structure must be considered a two-part rate, wherein the part based on usage consists of a single step. It is a two-part rate because a substantial part of the capital costs of the project were paid from tax revenues; consequently, the "usage" part of the rate is required to produce only enough revenue to meet debt charges of the part that was financed through sale of revenue bonds and to meet operating expenses and reserve fund requirements.

A single-step for the "usage" part of the rate was adopted for the reason that the entire charge is for treatment and disposal of sewage that is picked up by the interceptors; consequently, the cost of treating and disposing of any given unit of sewage is identical to the cost of treating and disposing of any other unit, regardless of whether the unit was contributed by one large contributor or many small ones.

Consideration was then given to the problem of whether the charge should be billed on a separate bill form, or as a separate item on the water bill, or included in the water bill. For reasons of economy it was decided to include the sewage disposal charge in the water bill and to make a clear explanation of this combined billing on the bill form. This choice of procedure has made it possible for the department to take over the job of billing, collecting, and accounting for sewage disposal charges without any additional expense. In general, customers have understood the additional charge for sewage disposal and the combined form of billing, with the result that there has been no appreciable effect on customer relations. However, it did necessitate the preparation of a plan that could be depended upon to effect a complete and accurate segregation of water and sewage disposal receipts.

The question was then considered as to who should be held responsible for sewage disposal charges. Inasmuch as water charges in Detroit are a lien against the property served, the sewage disposal ordinance was drawn to make the sewage disposal charge also a lien and enforcible in exactly the same manner as is the lien for the water charge.

The next question considered was that of determining a satisfactory means of forcing payment of sewage disposal charges. Although the right of lien is a formidable weapon for use against delinquent customers, it is a most cumbersome and costly one because of the expense of foreclosure, which usually exceeds, to a considerable extent, the ordinary sewage disposal or water charge. Its principal value lies in its ability to fix responsibility and depends largely upon some other agency to force actual collection. The perfect combination is the right of lien to establish liability and the right to discontinue the sewer service or water service to the property for nonpayment of the sewage disposal service. The Detroit ordinance was drawn to provide for all of these measures.

Detroit makes a charge for sewage disposal service to all properties that are connected to the system, on the basis of water consumed, making adjustments under the following rule adopted October 20, 1941:

> The Sewage Disposal rate shall be applied uniformly to all water consumers, whose property is connected to the Sewage Disposal System, on the basis of the quantity of water used thereon or therein, regardless of the purpose for which the water is used, or the character or concentration of the sewage delivered from the property to the Sewage Disposal System, except that an additional charge may be made where the character of the sewage is such that it imposes an unreasonable burden upon the system, as provided for in the city ordinance; provided, however, that upon proper showing, exemption of the sewage disposal charge will be made on water delivered through a metered line where the entire amount of water delivered through said line is used for such a purpose, and in such a manner as to establish beyond reasonable doubt the fact that the water so taken does not enter the Sewage Disposal System.

Of particular interest is the fact that, since the sewage disposal charge has been in effect, less than thirty requests have been received for adjustment of the sewage disposal charge on the grounds that all or part of their water consumption did not reach the sewer. In general, the requests for adjustment were from railroads and large industrial plants.

An ordinance was passed by the Common Council requiring users of private wells, or any other private sources of water supply, to meter or measure such supply in a manner satisfactory to the Department of Water Supply, as a means of determining the proper charge for sewage disposal service. The regular sewage disposal charge is applied to water supplies from private sources.

Contrary to a rather widespread opinion that sewage disposal charges are difficult to collect and, that if added to water bills, would tend to slow up water collections, experience in Detroit indicates that inclusion of the sewage disposal charge in the water bill has had little if any effect on collections. As a matter of fact, the department's customer delinquent balance in October, 1941, hit a new low for the preceding thirteen-year period, in spite of the fact that the delinquent balance since June 19, 1940, carries sewage disposal charges as well as water service charges.

HERBERT MOORE,[5] ASSOC. M. AM. SOC. C. E.—The organization of large sanitary districts is the subject of this paper, such districts being required because of the "magnitude and difficulty" of projects for sewage treatment. Often, however, a need for relatively simple sewerage improvements can be met by the organization of a small sanitary district.

---

[5] Cons. Engr., Milwaukee, Wis.

In Wisconsin, enabling legislation makes this possible. Some forty sanitary districts have been organized under Wisconsin statutes 60.30 to 60.309, in unincorporated township areas. Districts have been formed for the most part to provide sewers only, in order to discharge sewage into the system of a neighboring incorporated community or metropolitan sanitary district. However, several small sanitary districts provide their own sewage treatment.

The first step in the organization of a sanitary district is a petition to the town board signed by at least 60% of the property owners of a given area. Following a public hearing, the town board establishes the boundary and appoints three commissioners at a nominal fee (generally about $25 each per year) to administer the district. The district may then construct sewerage improvements and finance the project by bond issue.

Thus, a sewerage and sewage disposal system serving a small suburban residential community in Metropolitan Milwaukee (Wis.) was constructed by the Westchester Sanitary District, Town of Brookfield, Wis., Waukesha County, and placed in operation in December, 1941. This project provides the main sewers, a sewage disposal tank, and sewer connections from house building lines. It is believed to be the first public sewerage and sewage disposal system to be constructed from homes through the disposal system complete. Furthermore no federal aid was received.

Located about one mile west of the limits of the area served by the Metropolitan Sewerage Commission of Milwaukee County, the Westchester Sanitary District was formed by the homeowners and residents of a housing community to correct nuisance conditions resulting from the use of septic tanks. Some forty houses had been constructed and septic tanks and gravel leaching beds were installed in accordance with best approved practice. However, soon after the houses were occupied, septic sewage effluent from the leaching beds emerged upon the surface of the ground, flowing into ditches and across neighboring property, thereby causing considerable odor and nuisance. The organization of the sanitary district resulted from the demand by property owners for immediate corrective measures.

Plans and specifications were prepared and advertised. The contract was awarded to the lowest of six bidders and the system, comprising some 8,000 ft of sewer lines and a concrete two-story-type tank, was constructed. Sewage effluent from the tank flows into a gravelly subsoil on the property of the District. Six months' time elapsed between the formation of the Sanitary District and the completion of construction of the project.

Work was financed by general obligation bonds in the amount of $4,200 and revenue bonds in the amount of $12,500, at interest rates of 2.4% and 4.5%, respectively. The general obligation bond issue was limited by statute to 5% of the assessed valuation at the time of the last previous assessment.

Francis H. Kingsbury,[6] M. Am. Soc. C. E.—An analysis of the various methods by which sewage treatment projects have been established, with particular reference to the organization and financing, is presented in this paper. Although three general types of organization are noted and consideration is given to various methods of financing, including reference to the trend toward service charges and revenue bonds, the writer believes that discussion of the various factors that can influence the selection of the type of borrowing may be appropriate.

---

[6] Associate San. Engr., State Dept. of Public Health, Boston, Mass.

The history of finance of the large investments for the Boston metropolitan sewerage districts and the change in the methods of public financing in Massachusetts since 1889 may be of interest. Until 1913 the general method of bonding in Massachusetts was that known as the "Sinking Fund Method" whereby the annual payments into a sinking fund plus the interest on the total bond issue remained at a constant total figure throughout the life of the bonds. A modification of this method of financing in the case of the North Metropolitan Sewerage District and the South Metropolitan Sewerage District, noted in Table 1, was adopted for the purpose of permitting a series of increasing annual payments for financing to parallel, as nearly as might be the estimated, future increases in population.

Chapter 439 of the Acts of 1889 and Chapter 424 of the Acts of 1899 of the Massachusetts General Court provide that:

> "* * * The treasurer or receiver shall, on issuing any of said scrip or certificates of debt, apportion thereto from year to year an amount sufficient with its accumulations to extinguish the debt at maturity; but any such apportionment or assessment shall be at the rate of one eightieth part of the whole amount in each of the first ten years, one sixtieth part in each of the second ten years, one thirtieth part in each of the third ten years, and the remainder equally divided in the next ten years * * *."

Since the population more than doubled during the life of the bonds, this method of financing was fortunate because it maintained a reasonably uniform per capita assessment.

Beginning in 1913 the Commonwealth adopted the serial bond method whereby bonds are issued for different periods of time to provide for payments on the principal each year in amounts as nearly equal as possible, with the further provision that no annual payment on the principal shall be less than any subsequent payment. The effect of this method of finance is to make the total requirements for interest and principal the greatest in the beginning, gradually decreasing to the last payment which includes its portion of principal and a relatively small charge for interest. Difficulties were experienced in meeting the first annual payments on new projects before revenue began to come in, and, in certain instances, special legislation permitted deferment of the annual payments on account of principal for a period of three to five years to delay the peak assessments.

The change from the sinking fund to the serial bond method was brought about by two general considerations:

1. The unfavorable experience with municipal sinking funds sometimes invested by financially inexperienced municipal officials;

2. The trend from private to public enterprise in many services which was having a tendency to pyramid annual expenses of municipal governments; and

the desire to accomplish the payment of a considerable portion of the principal of any borrowing before some new enterprise might be voted.

Fig. 2 shows a comparison of the annual payments for principal and interest by the sinking fund, modified sinking fund, and the serial bond methods of borrowing.

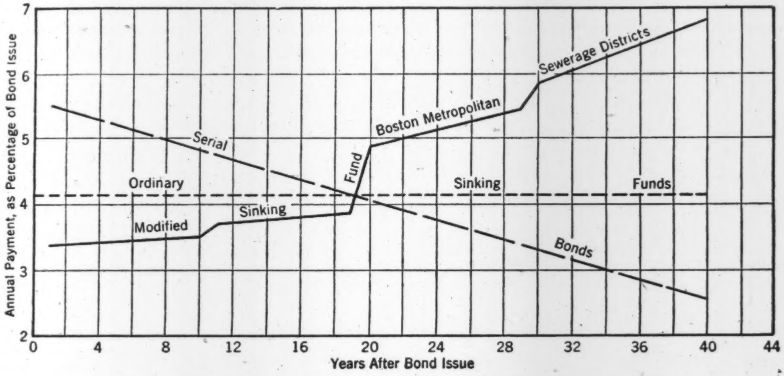

FIG. 2.—COMPARISON OF DEBT SERVICE FOR FINANCING BY VARIOUS METHODS OF BOND RETIREMENT (Interest Assumed at 3% Per Annum)

In financing a new project for sewage collection or sewage treatment, a careful analysis should be made of the probable future charges and their relation to probable population changes and to probable needs, not only for the project under consideration but for other municipal improvements. It might happen that a large initial assessment could defeat a project if it were financed by serial bonds requiring the largest payments in the beginning and that selection of the sinking fund method or a modification of the sinking fund method would be more appropriate. On the other hand, there are many projects for which the population is likely to be more or less stabilized, in which case the ordinary sinking fund or the serial bond method might be more appropriate.

A. BRINTON CARSON,[7] ASSOC. M. AM. SOC. C. E.—In his excellent paper Mr. Greeley states that the trend in the organization of sewage treatment projects has been independent of other local governments; but it appears, from his paper, that the trend proceeds at a snail's pace. It also appears that the existence of such a trend at all is due, not to the practical considerations of engineering, but to the legal exigencies of financing.

The evils of organizing sewage treatment projects along purely municipal or local governmental lines have always been apparent; so too have the engineering fallacies to which this practice frequently leads. Mr. Greeley has indicated, either consciously or unconsciously, the difficulties encountered in large municipalities. Those encountered in small communities are frequently defined more sharply.

The most important of these difficulties is the problem of operation. Because small plants frequently discharge their effluent into small streams, the required degree of treatment is generally higher than for large plants discharging into larger bodies of water. Yet it is precisely for small plants that the greatest difficulty is encountered in securing properly trained operators. The difficulty, of course, is basically financial. The proper operation of small plants tends to increase the per capita cost of operation, sometimes seriously. It is apparent, therefore, that larger plants, or groups of small ones operated as a unit, could operate more efficiently and at a much reduced per capita cost.

---

[7] Lt., CEC-V(S), U. S. N. R., Philadelphia, Pa.

There are other difficulties in small communities, however. Consider the case of C and D, two small adjoining towns on the same watershed. Because they were unable to agree on a joint plan, each built its own treatment plant. Both plants were finally constructed 200 yd apart on the same bank of one stream. Consider also the case of A, another small town. Agitation for sewerage came from a part of A built on low ground along the banks of a stream. Just outside the town limits of A, and also on low ground, was a thickly populated area, not incorporated as a town, a part of the adjoining township. Town A provided its citizens with sewerage and sewage treatment. It was willing to take the sewage from the adjoining area and treat it, but could do so legally only by agreement with the adjoining township. The township refused to enter into any agreement for the benefit of this small area, since the remainder of the township was sparsely settled, and it was afraid of setting up a precedent.

It is noted that even the Illinois Enabling Act permits territories the freedom of choice as to whether they shall annex or disannex themselves to or from a drainage district. No thought is given to the effect of this freedom of choice on the remainder of the sanitary district. Where such a territory lies in the center of a natural drainage area, the effect of its withdrawal might be disastrous on the entire remaining sanitary district.

It is true that the reason for many of the difficulties now being encountered lies in the fact that sanitary engineering, in terms of civilization, is relatively new. The education, for great masses of people, as to its necessity has scarcely begun. It has been necessary, practicable, and advisable to construct sewerage facilities as opportunity offered—almost, it might be said, as an educational guide.

It is probably true that the educational phase is not yet over even in the United States; but, coincidental with the decline of that phase, there should be inaugurated a new phase of broad-scale planning in the organization and financing of sewerage and sewage treatment plant construction. If it is begun early it will be well done in the end; if it is begun late it may never be done at all. As a basis for such planning, the writer offers the following suggestions for an ideal design, with the thought that existing conditions and practical considerations be permitted to modify it only by the purest compulsion.

Organization.—

1. What is (or should be) the definition of a sanitary district?

A sanitary district may be defined as a section of the earth's surface consisting of the whole or part of a natural drainage area or a series of such areas draining into a common basin.

2. How extensive should a sanitary district be?

A sanitary district should be large enough to warrant the construction of a sewage treatment plant with a capacity of at least 1,000,000 gal per day when the present density of the population in the area is 20% or more of the probable ultimate density. This arbitrary definition will be further modified by certain other factors such as:

(*a*) The availability of a plant site of sufficient size for present construction and future extension.
(*b*) The average slope of the basin. Where the average slope is relatively flat the district may be limited by the time required for sewage to reach the plant in a sufficiently fresh state for proper treatment.
(*c*) Undulating or special terrains, such as a community in a flat desert area; communities built along a shore and isolated by salt marshes from the mainland, etc.

3. To what extent should existing local governmental boundaries be used in defining a sanitary district?

Pre-existing governmental boundaries should be used only where they happen to coincide with the boundaries of a drainage area. It is a purpose of this procedure to ignore all local governmental boundaries, and to consider the question of sewage entirely from an engineering point of view. It is believed that such a procedure will reduce operational costs as well as overlapping and duplicating efforts.

4. When should such a sanitary district be organized?

When the density of population of any part of the district warrants the collection and treatment of sewage. Further definitions might be set up covering this phase, but it is likely that the pressure of local opinion may be more potent.

5. Who should determine the area of a sanitary district?

It should be first approximately defined by that agency of the state government customarily charged with reviewing and passing upon proposed sewerage facilities. After the district has been organized, by the procedure outlined herein, preliminary surveys should define the area more exactly. The preliminary definition of the district is delegated to the state as being a disinterested party. The state is also considered as a centralizing agency having knowledge of the proposed organization of all districts in the same drainage area, as well as in adjoining drainage areas.

6. When should a state agency delineate a sanitary district?

On a petition from 100 qualified voters in a continuous area. It is assumed that a town or community would be the continuous area referred to.

7. How should a sanitary district be activated?

After a petition of 100 qualified voters has been referred to the state agency controlling sewage, the agency would define the approximate limits of the district. This information would then be referred to the executive branch of the state government, which would appoint three commissioners to supervise an election in the district. The state would be empowered to advance the costs of this election, from funds set up for this purpose (see subsequent heading, "Financing," regarding preliminary financing). The question to be determined by this election, of course, is that of whether the district shall be organized and sewage facilities constructed.

It is possible that, under certain conditions, it might be advisable to include in this election the selection of permanent members of the sanitary district board or commission. In other cases, assuming that the vote of the electorate is affirmative, it may be preferred to select the district board by a separate election or by appointment by the executive arm of the state. However, this step of the procedure, being entirely politico-legal, will vary from state to state.

The next step, after establishing a sanitary district board or commission, would be to proceed with a comprehensive survey of the sewage handling requirements of the district. On completion, this would be presented to the state agency for review and approval. It is assumed that the area might vary from that originally proposed by the state, but it is believed that it will seldom vary to such an extent as to affect, materially, the population included and thus require a new election.

When the state agency and the district's engineers have agreed on a comprehensive plan of the facilities, area, etc., the district is then in a position to consider costs and methods of financing.

8. What jurisdiction should a sanitary district board have?

A sanitary district board should have full jurisdiction over the collection and treatment of all sanitary wastes within its area. This should include existing facilities as well as those proposed. Storm drainage, except where it is incidental to sanitary sewerage facilities, should remain a function of existing governmental bodies. The acquisition and operation of existing sanitary facilities will constitute a special problem in every case. Additional study, in general terms, should be given to this phase.

The treatment (and transportation) of prime industrial wastes should be limited to a percentage of the total volume of sewage to be treated. That percentage should be the quantity which a plant designed for sanitary sewage can absorb without impairing its operation. Where prime industrial wastes are treated at the source they become secondary industrial wastes. A larger percentage of secondary industrial wastes might be permitted.

In general, then, the jurisdiction of a sanitary district board should be complete over all sanitary sewerage and treatment or anything which might limit or interfere with, or affect, the cost of such treatment.

9. What powers should a sanitary district have, when fully constituted?

Its powers should include the following:

(*a*) To fix the extent of present and future requirements of sanitary sewage facilities for the area, and to engage the necessary professional guidance for so fixing.
(*b*) To own, construct, or acquire such facilities as may be required.
(*c*) To operate facilities so acquired.

(*d*) To finance the construction or acquisition of such facilities by the acceptance of grants, the issuance of bonds, or such other means as can be made available.

(*e*) To make such charges for the collection and treatment of sanitary sewage as shall be found necessary to provide for adequate operation and for the retirement of indebtedness.

10. How should these powers be vested in the sanitary district?

By appropriate state legislation.

Financing.—

11. How should the early stages in the establishment of a sanitary district be financed?

The legislative act providing for the creation of sanitary districts should provide for an appropriation from state revenues. This appropriation should be used as a revolving fund for the purpose of advancing funds for elections, comprehensive surveys, etc. (but not including the acquisition of facilities), to bridge the period until permanent financing has been obtained by the district. From its financing, the district would then repay to the state moneys so advanced. In cases where the district failed to complete its organization, the state would carry the funds so advanced as a charge against any such future organization.

12. How should the construction and acquisition of sewage treatment plants be financed?

The cost of the construction and acquisition of sewage treatment plants, pumping stations, main trunk connecting sewers, outfall sewers, etc., is essentially a function of area—first, because the system is an asset not merely to the part of the district being immediately sewered, but also to those parts having no immediate need for individual sewerage; second, because modern design, no matter how limited the proposed present construction, provides for considerable extension of use before additional facilities must be constructed. There is, therefore, no equitable basis for distributing these costs except on the basis of area.

Financing by taxation on assessed value is not equitable because the value of property does not necessarily reflect its requirements for sewage facilities. Assessments based on present usage requirements are likely to work to the disadvantage of those for whom facilities are provided at a later date, or vice versa.

The owner of a hundred acres presumably can use present facilities without new construction if he should develop the property. Therefore, it follows that the costs of sewage treatment plants, etc., should be assessed on an acreage basis for all area within the district. If later development within the district requires additional construction of this type, the additional cost should again be assessed on area.

13. How should the cost of branch sewers (that is, collection systems) be financed?

The cost of branch sewers is essentially a function of accessibility or possible use. Therefore, it is a function of frontage. It follows that the cost of branch sewers should be assessed on the frontage served. Assessments should be based on the cost of an average 8-in. or 10-in. sewer at average depth. Where trunk sewers are available for individual connection, only the cost of the standard branch sewer should be assessed against frontage, the remainder of the cost being carried under paragraph 12. Costs of connections to the line of the property should be assessed against frontage on the same standard basis, such as 1 per 50 ft of frontage or, for singly-owned properties, a fraction thereof.

14. How should the cost of operating and maintaining the sewerage and treatment facilities be financed?

The cost of operating and maintaining a sanitary sewage system is essentially a function of use. Therefore, its cost should be charged against those who use it. Data presented in the Third Progress Report of the Committee of the Sanitary Engineering Division on Sewer Rental Laws and Procedure[8] indicate that use rates are of three types: (*a*) A flat rate per connection, (*b*) a rate based on water consumption, and (*c*) a rate based on fixtures or type of connection. A flat rate is necessarily limited in application to relatively small communities with a uniform density of population. It is therefore unsuited for use in the proposed sanitary district.

Rates based on water consumption presuppose the accessibility of water records to the sewer authority. In the proposed sanitary district, this might frequently not be the case. Several different water suppliers, in some cases privately-owned water companies, might contribute to the sewage flow. As a standard method of rate fixing, therefore, water consumption is not universal enough in the possibility of its application. There is the additional factor that, with water consumption as a basis, the actual use and the presumptive use may vary widely. Extensive and unnecessary collection and treatment facilities may have to be provided which will not be used, due to the knowledge that, so long as they are not used, in terms of water, there will be no charge for these stand-by facilities.

It appears that the most equitable basis for sewage rates is that which examines and adheres the most closely to the probable use. The number and the type of fixtures, conditioned by their location as to residential or industrial use, appear to distribute the cost of operation and maintenance most satisfactorily and are the most available for universal application.

15. How should the collection of charges for sewage service be organized in a sanitary district?

A sanitary district is conceived, herein, as an administrative organization. To avoid, as fully as may be possible, the duplication of existing functions already organized, it is proposed not to authorize the sanitary district board to collect directly from the individual sewage contributor. The sanitary district would establish the assessments and rental charges, but the actual billing and collection would be in the hands of the several local governments or portions thereof that might be part of the sanitary district. They, in turn, would make periodic returns to the district. This would permit the inclusion of assessments on tax bills and, at least in certain cases, rental charges on water or other service bills issued periodically. A nominal fee for collection could then be deducted from returns to the district by the local governmental body.

---

[8] *Proceedings*, Am. Soc. C. E., November, 1942, p. 1585.

Summary.—It has been the intention, in the foregoing, to propose a broad-scale plan for the organizing and financing of sewage works programs. Mr. Greeley's paper has indicated the extent to which similar planning has progressed in Illinois and some of the difficulties encountered there. From Mr. Greeley's paper, it is evident that even the Illinois Enabling Act is a compromise of political and legal expediency and that the careful planning of the engineer has been only an afterthought. Any enabling act, of course, is better than none at all, but it is the writer's thought that the engineering profession should be prepared to propose its own enabling acts in the future.

Samuel A. Greeley,[9] M. Am. Soc. C. E.—The discussions of this paper have covered a considerable range. That submitted by Mr. Adams is a good record of a practical experience in the accomplishment of sewage treatment on a regional basis by separate organizations. Experiences of this kind are useful in developing better methods of organizing and financing such projects.

Mr. Smith describes the procedure followed in determining the method of financing the Detroit (Mich.) sewage disposal project. He calls attention to one matter of importance and that is the approximation of a two-part rate in which one part is designated as a charge for usage based on metered water consumption and a second part is based on the financing of general obligation bonds by a property charge or tax. Sometimes this division approaches an equitable distribution of the cost and should not be overlooked.

Mr. Moore describes the successful organization of a small sanitary district. There are undoubtedly localities where a small sanitary district meets the requirements; but it seems likely that, in general, the duplication of governmental units for small populations is not desirable.

Mr. Kingsbury gives a clear illustration of the effect of the type of bond and method of borrowing on the annual cost illustrating, for instance, the difference between an equal total annual cost and an equal per capita annual cost. Fixed charges of this kind should be related to the annual sums set up for depreciation and the method of allocating major repairs or replacements as between capital and operating accounts. Consideration should also be given to the lower total expenditure in dollars with serial bonds as compared to sinking fund methods. Presumably the serial bond maturities and interest rates can be adjusted to approximate equal annual total amounts. Frequently, however, general constitutional or charter provisions limit the choice, and the type of borrowing cannot be arranged to meet favorably different local conditions.

The discussion by Lieutenant Carson is of marked interest and describes a procedure for an ideal design in organizing and financing a sewage treatment project. The first seven sections under "Organization" relate primarily to the determination of the extent, area, and need of a sanitary district. In this connection, attention should be called to Chapter 112, Laws, Session of 1910 of the State of New Jersey. Paragraph 2 of this chapter authorizes governing bodies of any two or more municipalities in the state to unite and jointly cause to be made at their joint expense, by competent engineers, surveys, maps, plans, reports, and estimates of proposed works. This is a good method and should be used more widely. In the writer's opinion, the comments by Lieutenant Carson on methods of financing are somewhat limited, as full consideration is not given to the difference between systems handling sanitary sewage only and those with capacity for storm sewage as well. His description and outline of an ideal procedure, however, is very stimulating.

PHYSICAL PROPERTIES THAT AFFECT THE BEHAVIOR OF STRUCTURAL MEMBERS

By Wilbur M. Wilson,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Jonathan Jones, A. B. Kinzel, Almon H. Fuller, C. F. Goodrich, R. L. Moore, Leon S. Moisseiff, Fred L. Plummer, A. A. Eremin, and Wilbur M. Wilson.

Synopsis

The physical properties of structural steels usually prescribed by specifications are the strength and the ductility. It is reasonable to infer that, if certain physical properties are prescribed, there must be some quite definite relation between these properties and the behavior of structural members. The purpose of this paper is to discuss this relation and to raise the question as to whether or not there are other characteristics of the material that should be considered.

Why Ductility Is Necessary

The two properties universally prescribed (and the only ones usually prescribed) for structural steels are strength and ductility. The value of high strength is self-evident. The value of ductility is so general that some discussion would seem to be in order. Engineers generally agree that ductility is necessary for the following reasons:

(1) To prevent fabrication and erection operations from breaking or weakening the members;

(2) To permit members that are slightly bent in handling to be straightened cold without injury;

(3) To enable plastic deformation to effect a more nearly uniform distribution in regions of concentrated stress due to inaccurate fabrication, thermal stresses due to welding, or other causes;

(4) To reduce greatly the extent to which moderate deformation stresses and load stresses are additive beyond the yield point; and

(5) To give the structure a shock-absorbing capacity that will enable it to withstand accidental shocks of considerable magnitude that are not quantitatively provided for in the design.

Note.—Published in December, 1942, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Research Prof., Structural Eng., Civ. Eng. Dept., Univ. of Illinois, Urbana, Ill.

All of these actions involve one or more occurrences in limited areas of deformation stress, exceeding slightly the yield point of the material.

(The term "deformation stress" is not in general use and an explanation of its meaning is in order: As the term is used in item 4, a deformation stress is a stress incident to a deformation, as distinguished from a load stress which is incident to a load. The vertical shear in the outstanding leg of the connection angles of a stringer is a load stress because it results from the load carried by the stringer. If the outstanding leg were to fracture because of the shear, the end of the stringer would fall. As distinguished from this action, the outstanding leg of the same angle is subjected to flexure because of the deflection of the stringer. This flexural deformation produces stress; but if

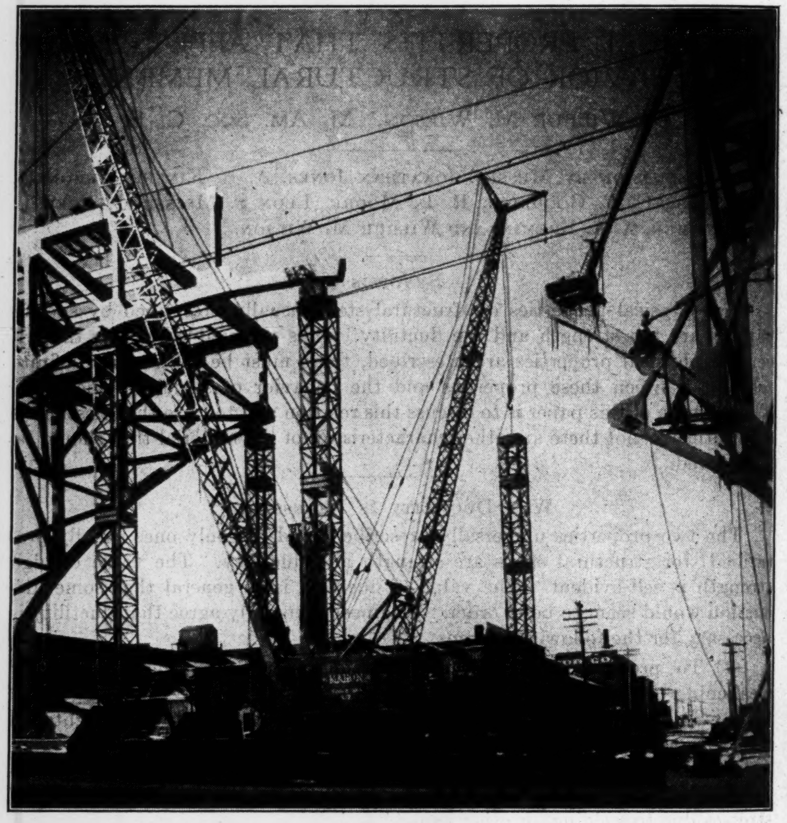

FIG. 1.—SUCCESSFUL CONSTRUCTION REQUIRES THE USE OF A STEEL TO WITHSTAND OVERSTRESS WITHOUT SERIOUS INJURY TO MEMBERS. CONSTRUCTION VIEW OF A HIGH-LEVEL VIADUCT OVER THE CUYAHOGA RIVER AT CLEVELAND, OHIO

the outstanding leg were equipped with hinges at both vertical edges, the necessary movement could take place without producing flexural stresses in the outstanding leg of the angle, and the connection angle would still hold the stringer in position. This latter case illustrates a primary characteristic of all deformation stresses, which can be stated as follows: If the movement which caused the deformation stress could take place without stress, the load-carrying capacity of the structure of which the member under consideration is a part would not be appreciably affected.)

Hazards of Fabrication and Erection (*Item* (*1*)).—Stresses slightly in excess of the yield point probably occur in most structures during fabrication and erection. Successful construction requires the use of a steel to withstand this overstress without serious injury to the members. For this reason, engineers, in general, consider the capacity of structural steel to elongate 1% or 2% at the yield point, without any appreciable increase in stress, to be one of its most valuable characteristics. This plastic deformation is twenty-five times the elastic deformation corresponding to usual design stresses, but standard A7 carbon steels[2] and a number of low-alloy structural steels can be subjected to this deformation without being stressed appreciably beyond the yield point. Moreover, if a steel originally capable of being elongated 25% is elongated locally 2% during fabrication, it still will retain more ductility than it is feasible to utilize. Furthermore, tests showed that an A7 steel, after being subjected to more than 2,000,000 repetitions of a cycle in which the stress (tension) varied from 25,000 to 50,000 lb per sq in., retained its original static strength, and practically all of its original ductility, although its yield point was raised. (The first application of this stress produced a plastic deformation of the order of 4% or 5%.[3]) There is a possibility, however, that age embrittlement may develop in some steels subsequent to plastic deformation. The possibility of this action taking place in structural steels has not been studied in a comprehensive manner.

For a half century, carbon structural steel similar to A7 has been successfully fabricated by riveting. Low-alloy structural steels have been fabricated, but to a lesser extent. Experience with both of these steels would seem to justify the conclusion that they are suitable for structural purposes after being subjected to the overstress incident to fabrication by riveting. Nevertheless, it would seem desirable, particularly with the low-alloy steels, to make comprehensive studies to determine the extent to which their ductility is reduced by age embrittlement subsequent to plastic deformation.

The foregoing comment pertains to the results of overstress incident to fabrication by riveting. During the past decade the structural engineer has been compelled to accept oxygen cutting and welding as fabrication processes because of their economy and convenience. An A7 carbon steel, with carbon and manganese content limited to 0.25% and 0.70%, respectively, can be welded without serious metallurgical damage, and specifications[4] have been adopted for the welding of highway and railway bridges.

---

[3] *Bulletin No. 327*, Univ. of Illinois Eng. Experiment Station, Urbana, 1941, p. 32.

[4] American Welding Society's 1941 "Specifications for Welded Highway and Railway Bridges."

The effect of oxygen cutting and welding upon structural steels may be summarized as follows:

(*a*) If carbon structural steels similar to A7 are oxygen-cut with a mechanically guided torch, the resulting edges will give tests equal to planed edges, but evidence is not available to justify a similar statement relative to low-alloy steels.[5]

(*b*) Although welding and oxygen cutting, when properly done, do no serious metallurgical damage to carbon structural steels with certain limitations of carbon and manganese content, they may result in serious injury to members subjected to repeated or reversed stresses. Surface irregularities or abrupt changes in section are serious "stress raisers" that greatly reduce the fatigue strength of a structural member. The indiscriminate use of oxygen cutting and welding may result in rough edges or abrupt changes in section, with an accompanying serious decrease in the fatigue strength of the member.

(*c*) Low-alloy steels can be oxygen-cut and welded, provided that the proper procedure is followed, but if the proper procedure is not followed the resulting member may be much more unsafe than a similar member fabricated of carbon steel; furthermore, the possibilities of serious damage are not limited to major operations. The welding of a small, incidental piece to a large member to facilitate erection (a process not supposed to affect the strength of the structure) may embrittle the member or actually cause a fracture before any external load is applied. Similarly, cutting a handhole in the web of a channel or I-beam may embrittle the member. These are the results of metallurgical damage. The damage is all the more dangerous because it results from a minor operation that may not be given serious consideration. No oxygen cutting or welding of any medium-carbon or high-carbon steels or any low-alloy steels should be done except in complete accord with the procedure developed for the particular steel in question, and then only under competent supervision.

Errors in Workmanship (*Item* (*3*)).—The plastic deformation at the yield point that prevents a member from being injured by the fabrication processes also effects a redistribution of uneven stresses and greatly reduces the extent to which load stresses and moderate deformation stresses are additive beyond the yield point. (This might not be true under a triaxial stress condition.) Errors of workmanship, structural members that must be forced into line, and thermal stresses due to welding are common sources of uneven stress distribution. The mechanism of this stress redistribution is apparent from the behavior of a column whose reinforcement is attached with longitudinal fillet welds. Measurements on columns with an $\frac{L}{r}$-ratio of 70, when reinforced in this manner, indicated that the thermal stresses due to welding were equal to the yield point of the material. Nevertheless, tests showed that the load-carrying capacity of the columns was increased in direct proportion to the increase in section.[6] This was possible because plastic deformation at the yield-point stress prevented the stress at any point from exceeding the yield point of the material by an appreciable amount. It also permitted low-stressed material adjacent to high-stressed material to limit the strain of the latter to a value only slightly greater than the elastic strain corresponding to a yield-point stress. Moreover, the high-stressed material was supported laterally by the adjacent low-stressed material. The action of a similarly reinforced tension member is much the same except that the load-carrying capacity of the member might not be increased quite as much as the area of the section because the stress-strain relation would not be the same in the heat-affected zone as in the unaffected zone. However, the difference would not be great for an A7 steel.

[5] *Proceedings*, Am. Soc. C. E., April, 1940, p. 627.

[6] *Bulletin No. 280*, Univ. of Illinois Eng. Experiment Station, Urbana, 1935, p. 25.

The effect of superimposing a load stress upon a deformation stress is similar to the effect of superimposing a load stress upon a thermal stress. In fact, a thermal stress is a deformation stress—a stress resulting from motion, or from the prevention of motion, as distinguished from a stress resulting from a load.

The action of a member reinforced without removing the dead load is similar to the action of a member to which reinforcement is attached with longitudinal fillet welds in that some portions of the section are stressed higher than other portions and in that a redistribution of stress takes place when the maximum stress reaches the yield point.

The stresses in the members used in the foregoing illustration exceeded the yield point of the steel over some portions of the section. The writer has taken the position that, in many situations, this high stress does not endanger the safety of the structure, for the following reasons:

(*A*) In each instance, the stress in excess of the usual design stress is due to a deformation, and this deformation is limited in magnitude to a value only slightly exceeding the elastic deformation corresponding to a yield-point stress by material other than the material that is overstressed; and

(*B*) The deformation at the yield point that equalizes local stress concentrations does not seriously injure carbon and some low-alloy structural steels.

Approval is given to the action described, subject to certain limitations, not with the idea of deliberately overstressing material in new construction, but with the idea of possibly retaining old structures in service which have deformation stresses due to foundation movements or which must be reinforced because of an increase in the loads. Even for this purpose, combined deformation stresses and load stresses equal to the yield point of the steel cannot be accepted for compression members for which the deformation will cause local wrinkling failure or for which eccentricity of the resultant stress will introduce objectionable flexural stresses in the column as a whole. Likewise, a high, combined, load-and-deformation stress cannot be accepted in a tension member that has a reduced section at a point of maximum stress. Such stress will cause the strain resulting from movement to be concentrated at the reduced section instead of being uniformly distributed over a considerable length, as it would be if the section were uniform.

Accidental Shock (*Item* (*5*)).—A fifth reason why ductility is an essential property of structural steels is that it gives the structure a shock-absorbing capacity that will enable it to withstand accidental shocks of considerable magnitude that are not quantitatively provided for in the design.

Some further explanation would seem necessary to convey a clear conception of this contemplated action. As ordinarily considered in the design of railway bridges, impact consists of the dynamic increment resulting from unbalanced wheels, "out-of-round" wheels, track irregularities, etc. These produce stresses in the members of a bridge, and a member is so designed that when impact stress is added to dead-load and live-load stresses the total does not exceed 18,000 lb per sq in., a value considerably less than the yield point of the material. In other words, the impact that is known to exist, and which is evaluated in the design, produces an elastic deformation of the material. This impact is to be distinguished from an accidental shock (such as might result from a derailment) that is unknown in amount and may be so great that it will bend or break a member. One occurrence of such a shock would cause failure in a tension member made of a brittle material and would cause permanent deformation in a member made of a ductile material. Failure of the brittle member might cause the collapse of the entire structure, whereas permanent deformation of the ductile member, in most instances, would require nothing more serious than its replacement.

In general, engineers recognize the value of a shock-absorbing capacity in a member that will prevent the collapse of the structure as a whole, due to a large accidental shock, but they are not willing to add material to the structure merely to provide safety against this unpredictable action; nor would this seem to be necessary. The proper solution of the problem would seem to be:

First, design the structure so that all loads and forces that are expected to come upon the structure, and which can be evaluated, will be resisted at stresses well below the yield point of the material (this is designing for strength); and

Second, use a material which, in providing the required strength, will also provide the greatest possible shock-absorbing capacity. Then, even though the magnitude of some possible accidental shock cannot be anticipated, provision will have been made to guard against the destructive effect of the shock with the greatest economy.

These two steps, consciously or unconsciously, enter into the design of all structures. The second step is introduced when the use of a ductile material is required. A part of the second step that is not always recognized is that the shock-absorbing capacity of a member depends as much upon the geometrical characteristics of the member as upon the ductility of the material.

The shock-absorbing capacity of an A7 carbon structural steel is approximately one thousand times as great in the plastic range as in the elastic range. This is true only if the entire volume of the member is equally stressed when failure occurs. The truth of this statement is apparent from the stress-strain diagram for such steels. The work done in a tension failure is represented by the area under the stress-strain diagram. This varies for various specimens but may have a value of the order of 18,000 in-lb per cu in. The work done in stretching a steel to 0.8 of the ultimate equals the area under the stress-strain diagram up to a point representing that stress. Since this point is on the ascending portion of the curve, the area under the portion of the curve to the left of that point will be relatively small—usually of the order of 10% or 15% of the area under the entire diagram.

An effective net section of 80% by test[7] is as great as is usually realized in fabricating by riveting. When a riveted member fails in tension, only a small part of its total volume—that adjacent to a transverse section through the rivet holes—is stressed to its ultimate capacity and undergoes the full plastic deformation of which the material is capable. This small volume absorbs energy that is equal, approximately, to 18,000 in-lb per cu in. Much the greater portion of the volume of the member is stressed to only 0.80 of its ultimate capacity and undergoes a correspondingly small plastic deformation. The energy that this greater volume has absorbed when the weakest section fails is of the order of 1,800 in-lb per cu in. The average value for the entire member depends upon the rivet pattern, but is not likely to exceed 3,000 to 4,000 in-lb per cu in. This is the basis for the statement that the shock-absorbing capacity of a member depends as much upon the geometrical characteristics of the member as upon the ductility of the material. Mechanical engineers, in their treatment of bolts that fail due to shock, have long recognized the principle involved. Such failures are largely eliminated by turning down the body of the bolt to a diameter less than the diameter at the root of the thread.

The fact that some types of members have a greater percentage of gross volume that is effective for absorbing shock than others is the justification for using a less ductile steel for some types of structural members than for others.

Cables of suspension bridges are fabricated of wires that may have a yield point of 150,000 lb per sq in., an ultimate strength of 220,000 lb per sq in., and an elongation in 10 in. as low as 4%. Because the wire is of uniform section, the entire volume will be stressed equally, and the energy required to break the wire is of the order of 7,000 in-lb per cu in., a value twice as great as the entire shock-absorbing capacity of many riveted tension members fabricated from an A7 steel.

The eyebar is another fabricated member that has a high shock-absorbing capacity because the section is uniform over the entire length except for enlargements at the ends. The cables of the Florianópolis (Brazil) suspension bridge were fabricated of medium-carbon, heat-treated eyebars.[8] The specifications for these eyebars prescribed a yield point and ultimate strength of 75,000 and 105,000 lb per sq in., respectively, and an elongation of 5% in 18 ft. The design stress was 50,000 lb per sq in. The energy required to break one of these bars is of the order of 4,300 in-lb per cu in., a value somewhat greater than the corresponding value for a riveted member of A7 steel.

The foregoing examples would seem to justify the use of high-strength, low-ductility steels for wires and eyebars, inasmuch as the uniformity of section more than offsets the low ductility of the material in their effect upon the shock-absorbing capacity of the member. This being true, it would seem that it might be profitable to consider whether or not it is possible to devise other methods of fabricating structural members so as to conserve a greater part of shock-absorbing capacity inherent in the material instead of discarding from 50% to 80% of this capacity, as is now usually done when fabricating by riveting. Any expedient that is used to stress the member uniformly high over the main part of its length must result in a member that has no section weaker than the body of the member, which is to be of constant section.

Effect of Speed of Loading upon Tensile Properties of Steel

Engineers have formed their conception of the tensile properties of steels from static tests. The term "shock" implies motion; that is, rapidity of application of the force. Some engineers have a vague feeling that the resulting stress, because of its suddenness of application, is more injurious than a static stress of the same intensity. Whether or not there is any basis in fact for this feeling depends upon whether or not the speed at which a steel is strained has any significant effect upon either its strength or its ductility. In the previous section of this paper, the comment relative to the shock-absorbing capacity of members is based upon the assumption that the ultimate strength and stress-strain relations are not significantly affected by the speed of loading.

H. C. Mann[9] reports tension tests on four alloy steels loaded at various speeds, to 28.5 ft per sec. His discussion of the tests contains the following paragraph:

> "It has been shown in the data presented that when similar specimens of the same material are tested at normal temperature, under both static and dynamic conditions, the total energy values obtained from each are the same, provided the velocity of impact is within a certain limiting amount, and that when this velocity is exceeded the impact values become considerably reduced. A possible explanation of this phenomena is obtained from a further consideration of the mechanism of the static test."

The tests cited showed that the shock-absorbing capacity of SAE-1035 steel[10] began to fall off slightly at a speed of 25 ft per sec. In considering this velocity in its relation to what might be experienced in a bridge, it should be noted that the significant velocity is that at which strain occurs rather than that at which a train crosses a bridge or at which one body strikes another.

Mr. Mann used short cylindrical specimens of constant diameter contained between heads of larger diameter, and they were subjected to a high-speed tension test. A few high-speed tension tests were made at the University of Illinois on specimens with geometrical characteristics of structural members.[11] The specimens included 3-in. by $\frac{3}{8}$-in. plates without joints; similar plates with open, drilled holes; similar plates connected with butt welds; and others connected with riveted joints. The force was derived from a 2,300-lb steel block which fell 10 ft and impinged on a nut on the lower end of a 2-in. steel rod suspended from the lower end of the specimen. The results indicated that the shock-absorbing capacity was as great under dynamic loading as under static loading.

[11] "The Effect of Speed of Loading Upon the Ductility of Structural Steel," by Gordon L. Jeppesen, and "The Effect of Speed of Loading Upon the Ductility of Structural Steel," by Robert Zaborowski, theses presented to the Univ. of Illinois, Urbana, Ill., in 1938 and 1940, respectively, in partial fulfilment of the requirements for the degrees of Master of Science in Civil Engineering.

The results of these tests are highly significant to the designer of bridges and, although the work that has been done is only exploratory, it would seem that the discussion, "Why Ductility Is Needed," based on static tests, applies to high-speed loading, provided that the "limiting speed" in Mr. Mann's tests is not exceeded. It also would seem that an impact stress is no more destructive than an equal static-load stress, provided that the speed at which strain occurs does not exceed the limiting speed used by Mr. Mann. Additional high-speed loading tests are needed at both normal and low atmospheric temperatures.

Fatigue Failure

Structural members are designed for known loads, treated as though they were static, and are fabricated of a ductile steel to enable them to withstand shock. It is now known that members subjected to repeated or reversed loads may fail by progressive fracture (unfortunately designated as a "fatigue failure") and at a relatively low average stress. Moreover, it is known that the fatigue strength of small machined-and-polished specimens is not a dependable criterion of the fatigue strength of a structural member fabricated of the same material, and that the fatigue strength of a structural member does not necessarily increase with the static strength of the steel from which it is fabricated.[3,12]

The ordinary formulas of mechanics of materials have been developed mainly for the design of structural members subjected to static loads, and they almost entirely neglect to consider localized stresses due to nonhomogeneity of material and sudden changes of cross section in structural parts. There are many localized regions in structural parts where the stress is higher, sometimes several times higher, than that computed by the ordinary formulas for strength of materials.

Any cause which produces a localized area of high stress is called a stress raiser. Abrupt changes in section, notches, reentrant angles, grooves, screw threads, surface irregularities, and discontinuities such as cracks, holes, or inclusions are stress raisers. The effect of a round hole in a plate, and of other simple stress raisers, has been determined by mathematical analysis and studied by means of transparent models viewed with polarized light; but, because the effect of a stress raiser upon the fatigue strength of a specimen is a function of the size of the specimen and of the physical properties of the material, as well as of the stress raiser, these studies are of limited value in predicting the fatigue strength of a particular specimen. They are of real value, however, in determining types of geometrical stress raisers that are to be avoided.

The cumulative experiences of half a century indicate that there is little reason to fear fatigue failures in riveted carbon-steel chords of trusses, or other members subjected to relatively few repetitions of the maximum design stress, provided that the members contain no unusually severe stress raisers. There has not been sufficient experience to justify a similar statement relative to

---

[12] *Bulletin No. 302*, Univ. of Illinois Eng. Experiment Station, Urbana, 1938.

welded members in carbon steel or relative to either welded or riveted members of the low-alloy steels. Experience has demonstrated that riveted carbon-steel members subjected to a large number of repetitions of the design stress do fail in fatigue. Fatigue failures of similar details made of low-alloy steels may be expected.

A limited number of fatigue tests have been made on steel structural members.[3,12,13,14] More fatigue tests of both welded and riveted connections are needed, and they should be made on specimens as large and as nearly like the connections used in structures as it is possible to test. Tests are also needed to determine the impact-fatigue strength of structural steels, and these, likewise, should be made on specimens with the geometrical characteristics of structural members.

Shear-Slip Relation for Riveted Joints

The extent to which the shear on a riveted joint is resisted by the friction between the plates depends upon the tension in the rivets. Laboratory tests show that carbon-steel rivets with a grip of 3 in. consistently have a tension of 20,000 to 30,000 lb per sq in.[12] The shear required to produce slip between plates clamped together by such rivets is of the order of 20,000 to 25,000 lb per sq in. of rivet section, a value considerably in excess of the usual working stress for carbon-steel rivets. The tension in some low-alloy steel rivets with a 3-in. grip varied considerably with individual rivets and was as low as 5,000 to 10,000 lb per sq in. for some.[15] The shear required to produce slip between the plates was correspondingly erratic and low. In general, the tension in the rivet increased with the grip in both magnitude and uniformity, with a maximum value somewhat less than the yield point of the steel.

A short, properly driven rivet will fill the rivet hole but probably will have a low tension. Unless the end of a long rivet is cooled before driving, or unless it is tapered, it probably will not fill the hole, but will have a high tension. A rivet that either fills the hole or has high tension will be satisfactory in service if the rivet retains its tension.

The limited number of fatigue tests that are available on this subject indicate that the rivets or bolts of a joint will have a much higher fatigue strength if the shear is resisted principally by the friction between the plates than if it is resisted principally by shear on the rivets or bolts.[16]

Summary and Conclusions

This paper contains ideas, relative to the behavior of structural members, which have resulted from many years of experience in testing engineering materials and structural members. The writer has assumed that the reader is familiar with the literature on the subject but, in a few instances, reference has been made to tests that bore directly upon the particular question being studied. The ideas of the writer, discussed in the body of the paper, may be summarized as follows:

---

[13] *Bulletin No. 310*, Univ. of Illinois Eng. Experiment Station, Urbana, 1939.

[14] *Bulletin No. 317*, Univ. of Illinois Eng. Experiment Station, 1939.

[15] *Bulletin No. 337*, Univ. of Illinois Eng. Experiment Station, 1942.

[16] *Bulletin No. 302*, Univ. of Illinois Eng. Experiment Station, 1938, pp. 58, 63, and 64.

(1) Structural members should be designed for known forces and then checked against fatigue failure. They should be fabricated of a steel whose ductility, considered in conjunction with the geometrical characteristics of the members, will enable them to resist large, unpredictable shocks.

(2) The plastic deformation that occurs at the yield point without an appreciable increase in stress enables the steel to be fabricated and erected without serious injury, permits redistribution of uneven localized stresses, and reduces the extent to which load stresses and moderate deformation stresses are additive beyond the yield point. Although stresses somewhat greater than the yield point may result at some portions of some sections of the members, they will not reduce the load-carrying capacity of the member appreciably unless the member is made of a steel subject to age embrittlement subsequent to plastic deformation, or unless the conditions are such that the high stresses will cause buckling or local wrinkling of a compression member or excessive elongation at reduced sections of tension members. Additional information is needed relative to the susceptibility of structural steels to age embrittlement subsequent to plastic deformation.

(3) The shock-absorbing capacity of a member depends upon the geometrical characteristics of the member as well as upon the ductility of the steel.

(4) Impact stresses are no more destructive than static stresses of the same magnitude unless the rate of strain exceeds the "limiting speed" of the material, except for the possible effect of impact fatigue, about which practically nothing is known. Additional information is needed relative to the "limiting speed" of structural steel at various temperatures and when fabricated into specimens with various geometrical characteristics.

(5) Oxygen cutting and welding may be used in the fabrication of steel structures, but only under the most careful and enlightened supervision.

(6) Fatigue failures are not likely to occur in riveted carbon-steel chords of trusses, or other members subjected to relatively few repetitions of the maximum design stress, provided that the members contain no unusually severe stress raisers. There has not been sufficient experience to justify a similar statement relative to welded members of carbon steel or relative to either welded or riveted members of low-alloy steel. Carbon-steel members subjected to a relatively large number of repetitions of the design stress have failed in fatigue. Fatigue failures of similar details made of low-alloy steels may be expected. Additional fatigue tests of riveted and welded structural members of both carbon and low-alloy structural steels are needed. Impact-fatigue tests are particularly needed.

(7) A short, properly driven rivet will fill the rivet hole but probably will have a low tension. A long rivet, unless its end is cooled before driving, or unless it is tapered, will not fill the hole but will have a high tension. A rivet that either fills the hole or has high tension will be satisfactory in service if the rivet retains its tension.

DISCUSSION

Jonathan Jones,[17] M. Am. Soc. C. E.—The following discussion of a problem in structural design may be considered a corollary to the author's exposition. In the design of long riveted plate girders, it is frequently economical to construct the flanges of structural silicon steel[18] which, although more expensive per pound, ordinarily permits an increase in unit stress from 18,000 to 24,000 lb per sq in. with a proportionate reduction in section and weight. If, however, a proportionate increase be made in the shearing unit stress for the web plate, it frequently results in a plate undesirably thin as regards either future corrosion or the possibility of buckling. If the shearing unit stress is not increased over that for carbon steel and if a silicon-steel plate is used, an "extra" of some $20 per ton is paid for capacity in shear which cannot be utilized. If carbon steel is retained for the web, it is cheaper, is safe in shear, and is of adequate thickness; but, because of its interaction with the silicon-steel flange, its outermost fibers are inevitably stressed to almost 24,000 lb per sq in., or one third higher than specifications permit.

However, engineers now seem to be in general agreement on the propriety of the evidently economical construction, carbon-web and silicon flanges. As the author has stated, the justification is that not only the unit stress, but also the possibilities of deformation, must be taken into account. In an all-carbon girder, if underdesigning, under future loading, led to an increase of flange unit stress to 33,000 or 36,000 lb per sq in., both web and flange would enter the phase of plastic flow, and the girder would be in danger. In a girder with carbon-web and silicon flanges, however, any future overloading that might bring the flange unit stress to 33,000 or 36,000 lb per sq in. could not cause the web to flow, because the silicon flanges would still be 9,000 to 12,000 lb per sq in. below their yield-point stress of 45,000 lb per sq in., and would still be elongating under practically their original modulus. The carbon web is locked in a high-yield-point flange that will not let it flow, and without flowing it cannot fail, being a material of high ductility.

The author refers to the eyebar (evidently the forged-head bar of several generations' standing) as an advantageous form from the standpoint of energy absorption, the advantage arising from the lack of any spots or localities of reduced area. Attention might here be called to a description[19] of a different type of tension-resisting bar, in which reinforcing-pin plates were welded on to each end of a long flat plate. In the case described,[19] this bar proved more economical of manufacture than a forged-head bar, and it obviously possesses the characteristic praised by the author of having no point of reduced cross section from end to end.

The last two sentences of the "Synopsis" open up a wider field than that of which the author disposes. The vital question of correlation between uses to which a material is to be put, and tests specified for its acceptance, is suggested by the "Synopsis" but not conclusively treated in the paper. Tests for strength and ductility are shown to be appropriate in specifications for structural steel, but does the author answer his final question of "whether or not there are other characteristics of the material that should be considered"?

[18] Specifications, American Society for Testing Materials, Designation, A.S.T.M.-A94.

[19] "Test of Model of the Tacoma Narrows Anchorage Bar," by Bruce Johnston and H. J. Godfrey, *Welding Journal*, Welding Research Supplement, August, 1939, p. 253s.

For structural carbon steel, it may be stated safely that there are no other characteristics, unless and until new types of application must be considered; if, for instance, welding is contemplated, a test that would check directly on "weldability" might be wanted. In general, however, considering riveted bridges, buildings, and similar structures, years of experience and millions of tests have convinced the engineer that if structural carbon steel passes the routine tests for strength and ductility, it may be considered also to possess all of that dependability under adverse conditions which the engineer has learned to expect of it.

The danger lies in carrying the same reasoning, by analogy, over into the specifying of tests for harder steels and for other materials, where no such background of experience may yet exist. Carbon steel, with 60,000 lb per sq in. tensile strength and, say, 26% elongation in 8 in., can safely be subjected to 18,000 lb per sq in. average stress combined with some form of coped or otherwise suddenly altered cross section. Can some harder steel, with 80,000 lb per sq in. and, say, 18% elongation in 8 in., be used safely in the same notched form at some higher unit stress? Often not. Often, it would not safely carry the same unit stress as the carbon steel. A new requirement has been introduced by the sudden change of cross section—accommodation to point concentrations of stress. Will the routine tension and bend tests establish that such a power of accommodation exists? They will not.

Supplementary requirements are not always overlooked. Sometimes for a harder structural steel, a "drifting" test has been imposed, at least on occasional samples, if not in a routine way. In many instances, however, the end use and the acceptance test seem to be further apart than is logical. (In a "drifting" test, punched holes in a narrow bar with sheared edges are considerably enlarged by driving tapered pins, the measure of acceptability being the degree of enlargement before fracture at edge of hole or edge of bar.)

The end use of bridge cable wire is to withstand tension combined with a highly overstraining cold bend around a small-radius sheave at the anchorage, and also to withstand tension combined with heavy cross loading in cable bands and saddles. That the customary tensile and bend tests are not prima facie evidence of this characteristic was proved by the serious failure, in service, of wire that had passed such tests with ease, but that, by an innovation in the process of manufacture, had been rendered vulnerable to the critical conditions just named.

The end use of a bronze bushing or bearing plate is to withstand rubbing on steel under heavy pressure without excessive wear, and to withstand this without seizing or scoring despite considerable fault in the lubrication; but the specified acceptance tests cover sometimes compressive deformation and sometimes tensile strength and elongation.

The end use of arc-welding filler metal is to make a sound, strong, and ductile joint with the material to be welded, under a wide range of variables such as position and temperature; but the specified physical tests are made upon the filler metal as laid in and upon itself, under the most uniform and ideal conditions of deposition.

None of the situations just described need necessarily to be dangerous, but the frame of mind they imply is so. Danger is absent if and when a sufficient body of experience has been built up, to prove that, if the acceptance tests are passed, none of the truly important properties, even though the tests do not challenge them, can be absent. Prudence dictates a greater effort than is always in evidence, to make the acceptance tests fit the critical aspects of the end use; and the fact should be squarely faced that in many instances an increased cost of testing will have to be absorbed by the user.

A. B. Kinzel,[20] Esq.—The scope of this paper is very broad, and Professor Wilson is to be congratulated both for the conciseness of his treatment and for the closeness of his reasoning. In treating so broad a subject, general terminology is necessary. In fact, the terms used are so all-inclusive that they frequently are not defined with sufficient completeness. An unconscious change in breadth of a term may lead to unwarranted conclusions.

Because of this method of approach, there is a strong tendency in the paper to reach conclusions that are ultraconservative and give rise to implications which are even more so. Various engineering codes have proved to be effective. These codes have been prepared by conservative engineers, but do not engender the feeling, present in Professor Wilson's paper, that welding, cutting, riveting (under some conditions), and low-alloy steels are to be applied only with fear and trepidation. Certainly there is sufficient experience to indicate that, as in most engineering problems, there need be no such feeling after application of intelligent judgment. As the paper is reasoned very concisely, discussion of it requires considerable detail and close following of the text.

One of Professor Wilson's first pleas is for more information on strain-aging embrittlement of carbon and low-alloy steels. It has been well demonstrated that fully killed steels—either the silicon or aluminum types—are not subject to this phenomenon. This fact removes a very large part of steel from consideration. Most of the low-alloy steel is fully killed. As to those steels which are not fully killed and may or may not exhibit strain aging, it should be stated that forming, punching, drilling, and similar processes used in general construction, and particularly in preparation for riveting, produce more than sufficient strain to cause the phenomenon, and such strain is set up at points of high stress concentration. Nevertheless, as Professor Wilson well demonstrates, experience justifies the conclusion that such steels are suitable for structural purposes after fabrication by riveting. Although one must be in accord with any plea for more information on any subject, it would seem that there is no need for the implication that further information on strain-age characteristics is needed vitally for immediate engineering use.

The author then discusses welding and oxygen cutting and very rightly stresses the importance of surface irregularities or other stress raisers. Here again the matter of degree must be considered carefully. An ordinary sheared edge very frequently contains surface irregularities in the form of notches, and even minute cracks, which may be far more deleterious to fatigue strength than the broader, less sharp irregularities resulting from cutting or welding. In the discussion of the application of these processes to low-alloy steels, it is stated (see heading, "Why Ductility Is Necessary: Hazards of Fabrication and Erection (Item (1)) (*c*)") that, if the proper procedure is not followed, the resulting member may be "much more unsafe." The use of this phrase is typical of the kind of implication to which many engineers may object. It is necessary to consider low-alloy steels. One category of such steels, broadly characterized by having less than 0.14% carbon and a tensile strength of some 75,000 lb per sq in., shows ductility in the heat-affected zone not dissimilar to that of plain very low-carbon steels and very much greater than that of plain, medium-carbon steels. Professor Wilson's statement obviously is not intended to apply to that group. The other group, with tensile strength approaching 90,000 lb per sq in. or more, generally contains more carbon and does exhibit reduction in ductility caused by the heat cycle of normal cutting or welding. By following the proper procedure, particularly with the addition of pre-heating or post-heating by torch or otherwise, the reduction in ductility becomes a minor matter. The same applies to the incidental welding, but here still another factor enters the situation. Damage due to such incidental welding of a small piece to a large member or cutting a handhole in the web of a channel may produce very serious conditions, primarily because of the internal stress resulting from the operation, and this is of the same order of magnitude even when low-carbon steels are considered. Moreover, local stress due to riveting a bracket in place likewise may reach high levels. Thus, although the writer is in accord with the author's word of caution, it would not appear that the entire subject is one for major alarm nor that the need for proper procedure and competent supervision in such operations is restricted to welding or cutting.

---

[20] Chf. Metallurgist, Union Carbide and Carbon Research Laboratories, New York, N. Y.

Regarding the matter of uneven stress distribution produced by fabrication, it is regrettable that Professor Wilson has not included riveting as a source of uneven stress distribution. Again, with respect to the measurements of internal stress due to producing a structural column by welding, it should be emphasized that similar measurements made on rolled members show that internal stress in rolled members likewise reaches the yield point. Stress distribution well may be different, and, for that reason, welded members must be considered very carefully from the standpoint of locked-up stresses; but, to reach such a conclusion, requires much more knowledge than the simple fact that internal stresses of yield-point magnitude do exist. The effect of the heat-affected zone is mentioned in this connection together with the conclusion that the difference between zones affected and not affected by heat would not be great for A7 steel. Neither would the difference be great for any other structural steel delivered for use in the as-rolled or normalized condition.

Regarding deformation at the yield point to equalize local stress concentration, the statement (see heading, "Why Ductility Is Necessary: Errors in Workmanship (Item (3)) (*B*)") is made that it does not seriously injure "carbon and some low-alloy" steels and the writer is at a loss to know just why "all" low-alloy steels were not included with "all" low-carbon steels or "some" low-carbon steels not included with "some" low-alloy steels. This wording again illustrates the matter of unfortunate implication. Actually from the standpoint of the structure, when deformation does occur, stresses are relieved, and the structure is in a highly desirable condition. The danger appears when deformation does not occur at all because of three-dimensional stress conditions. Also, damage is imminent when, because of stress concentration, total deformation must take place over an extremely limited zone and the percentage elongation not only exceeds the yield point deformation but goes on to approach deformation corresponding to the ultimate strength of the material.

In setting up the general solution of the problem, the author cites design first and material second and asks for material which will provide the very greatest possible shock-absorbing capacity. Particularly apt is his emphasis on the fact that shock-absorbing capacity of a member depends as much upon the geometrical characteristics of the member as upon the ductility of the material. This matter of geometry deserves to be emphasized, as it is the essence of the attack on limitation of ductility by three-dimensional stress which probably has been the most potent factor in such few service failures as have occurred. In this connection, suspension-bridge wires and eyebars are examples of uniform stress distribution. In these cases there is almost pure tension —that is, almost complete absence of the three-dimensional effect—and these members pointedly emphasize the need for geometry because of three-dimensional stress effects as well as stress uniformity.

Referring to the section on fatigue failure, although it is true that the fatigue strength of a structural member does not increase necessarily with the static strength of the steel from which it is fabricated, it is likewise true that, given reasonable surface conditions and geometry, fatigue strength does increase with the static strength in most instances. It is stated that there is little reason to fear fatigue failure in riveted trusses or other members subjected to relatively few repetitions of the maximum design stress; and it also is stated that there is not enough experience to make the same statement regarding welded members in carbon steel or any members in low-alloy steel. Just how much experience would be necessary for such a statement is a matter of opinion, but it is highly significant that, among the few bridge failures which have taken place in the hundreds of welded bridges, particularly abroad, no one of them has been reported as a fatigue failure. A statement is made regarding a large number of repetitions of design stress which would produce fatigue failures in riveted carbon-steel members. The author also states that were these details made of low-alloy steels, "similar fatigue failures might be expected"; but the probabilities would be definitely less as the basic fatigue strength of the higher tensile low-alloy steels is higher than that of the structural carbon steels.

The summary and conclusions of the paper are naturally open to the same type of arguments as the foregoing. For example, in conclusion (2), it is stated that deformation stresses above the yield point will not reduce the load-carrying capacity of the member appreciably unless the member is made of a steel subject to age embrittlement. There is no evidence to indicate that, even if the member is subject to age embrittlement, its load-carrying capacity will be reduced by local yielding. In the case of some designs that well may be so. In the case of others, it is not true. It should be remembered that strain-aging embrittlement does not reduce pure tensile impact resistance unless the velocities reach the order of magnitude involved in ballistics. The fact that a specimen of steel which shows strain-aging embrittlement under notched impact tests will not show loss of ductility in a straight tension impact test should be emphasized and again gives weight to the author's plea for good geometry.

As for conclusion (5), it is unfortunate that, in view of all the arguments presented by Professor Wilson, riveting has not been included with oxygen cutting and welding among those processes which should be used only under the most careful and enlightened supervision. The statement as given applies to any fabrication operation. The need for supervision and control in welding operations is stated well in the various codes, and it certainly seems unnecessary to single these operations out from all the others. This is particularly true of cutting where the condition of the surface in general is much better than that generally obtained by shearing and where, in addition, such effects as may be produced are so close to the surface that a stress of appreciable magnitude in the third dimension cannot exist. It also seems to be unnecessary in view of the really vast experience with oxygen-cut members.

Welding and cutting are not as old in the art as riveting but rapidly are approaching a mature age. They may be misapplied just as any process may be misapplied, but the fact that there are no hidden menaces involved already has been well established by experience. Low-alloy steels are even newer in this picture, but they have been used commercially on an appreciable scale for well over a decade. Thousands of freight cars bear witness to their adequacy. Good engineering judgment should be applied to their selection and use. Structures built in accordance with such engineering judgment and existing codes are performing satisfactorily, and the engineers responsible for such structures need not be too disturbed by the possible existence of phenomena which are understood fairly well, even though, in some instances, these phenomena have not been measured quantitatively.

ALMON H. FULLER,[21] M. AM. SOC. C. E.—Matters of much interest to the designing engineer are dealt with in this paper although the full implications of them may be outside of his experience. It raises some questions, frequently overlooked, which need to be considered in revising specifications and in the designing of unusual structures.

The author states, in "Summary and Conclusions" (2), that "* * * Additional information is needed relative to the susceptibility of structural steels to age embrittlement subsequent to plastic deformation." The writer would expect age embrittlement to follow oft-repeated plastic deformations but not to follow the occasional overstress which results from fabrication and erection procedures, secondary stresses, and deformation stresses in general. As the effect of such overstresses is to produce a slight change in the material and to raise the elastic limit, it seems likely that, in many a case, a repetition of the condition which produced the overstress might keep the unit stresses within the raised elastic limit. When elastic stability was not established after the first overstress, it might be established in such a small number of overstresses as to restore elastic behavior without danger of embrittlement. Pending further researches on the subject it may be possible to make pertinent observations of existing conditions.

---

[21] Prof., Civ. Eng., Iowa State College, Ames, Iowa.

In the paper on "Theory of Limit Design,"[22] by J. A. Van den Broek, M. Am. Soc. C. E., as well as in the one under consideration, questions are raised and helpfully discussed which demand thoughtful consideration for those situations for which close designing is essential. The effect of both papers should be to allay and not to create any fear that material will not adjust itself to apparently unfavorable conditions wherever the design has been made intelligently.

Can it be possible that, for structural steel, some of the adjustment (perhaps plastic flow) really takes place within the range of stress called yield point, elastic limit, and even proportional limit? Concrete is accepted as imperfectly elastic, and therefore flow is recognized well within accepted working stresses. Steel is usually regarded as perfectly elastic although the physicists are doubtless correct when they assert that it is not. Although the plastic flow (or creep) at normal temperatures is too slight to be measured within the precision of the usual deformation apparatus within the time of laboratory readings, two publications[23,24] record deformations over several weeks' time which are clearly greater than would occur within an hour or so for the same unit stresses. In his "Synopsis," the author expresses one purpose of the paper "* * * to raise the question as to whether or not there are other characteristics of the material [steel] that should be considered." Not even the flow of concrete is great enough to make undesirable changes in the dimensions of a structure; but quite likely such flow does relieve local stress concentrations and thereby does contribute to satisfactory functioning of the structure as a whole. Is it not likely that the very slight plastic yielding of steel, within working stresses, also contributes to the best functioning of a steel structure?

C. F. Goodrich,[25] M. Am. Soc. C. E.—The author justifies the practice of reinforcing structural columns by attaching the reinforcement with longitudinal welds, even though the thermal stresses due to the welding are equal to the yield point of the material. He is careful, however, to give approval only to the idea of retaining such old structures in service as must be reinforced to carry safely increased loads.

The simplicity of welding reinforcing material on old structures, as compared to riveting, makes welding the ideal solution of the problem of strengthening overloaded bridges. Tests have shown that the high thermal stresses resulting from such practice do not necessarily impair the load-carrying capacity of the reinforced structure.

[24] *Bulletin No. 40*, Eng. Experiment Station, Ohio State Univ., Columbus, 1928.

[25] Chf. Engr., Am. Bridge Co., Pittsburgh, Pa.

A somewhat different problem is presented when two different steels with different physical properties are used for one new member. Long riveted plate girders have been built with a carbon-steel web plate and silicon-steel flanges. When designing the web plate to resist buckling, it is found that the shearing capacity of a silicon plate is not fully utilized and a carbon-steel plate is often more economical. Many engineers have questioned this practice because the carbon-steel web will necessarily be stressed the same amount as the silicon-steel flange, in which a working stress of 24,000 lb per sq in. is usually specified. Thus the determination of the capacity rating of such a girder presents a nice problem. A capacity stress for carbon steel of 0.8 times the 33,000 lb per sq in. yield point is 26,400 lb per sq in., which is only 10% more than working stress of the silicon flange; whereas a capacity stress for silicon steel of 0.8 times the 45,000 lb per sq in. yield point is 36,000 lb per sq in., which is above the yield point of the carbon web.

In the accepted theory of girder design, the web is assumed to take its proportion of the bending moment and will doubtless do so in a well-designed, well-built girder of carbon web and silicon flange under static loads up to the yield point of the carbon web. The expectation that the web will continue to take its proportionate part of the bending moment beyond this point or under repeated loads somewhat below this point would seem to be in the realm of wishful thinking.

The part of the web between the compression flange angles probably is locked there so that it cannot yield in compression because it will have no place to go. This hardly seems true, however, of the part of the web between the tension flange angles, or just outside of them, where necking down (which accompanies plastic yielding in tension) is not restrained by the clamping action of the flange angles, especially under repeated loads and the possible loosening of rivets. It seems more than probable that the carbon web, under these conditions, no longer could be relied upon to take its proportionate part of such overload. Thus, the silicon flange would have to take all of it. It is probably true that the silicon flange will continue to act elastically up to its yield point, provided rivets have not become loose and the girder is otherwise integral.

The question might well be asked: Would responsible engineers evaluate a girder with silicon flanges and carbon web to carry future overloading and to resist impact and fatigue as highly as they would a girder of the same make-up but with silicon web? The answer is probably negative. The entire matter then resolves itself into whether the engineer is willing to accept this loss of load-carrying capacity in order to effect the undoubted first cost economy of using the carbon web.

R. L. MOORE,[26] ASSOC. M. AM. SOC. C. E.—An excellent general discussion of the need for ductility in structural steels is presented in this paper. The author's ideas also are applicable to other materials than steel. Although the functions of ductility generally are recognized, it is difficult to place a quantitative value on the importance of this property or to establish limits within which it may be varied without sacrificing structural safety. The author's statement in the "Synopsis" implying a definite relation between prescribed physical properties, including ductility, and the behavior of structural members, seems to the writer to require some elaboration.

---

[26] Research Structural Engr., Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

As long as the structural engineer was concerned principally with the use of carbon steel, the question of ductility was not important. The present trend toward the use of less ductile alloy steels and nonferrous metals for special uses, however, particularly where weight saving is an important consideration, makes it necessary to examine ductility specifications more critically. The question of greatest interest is not, "How is ductility useful?" but rather, "How much ductility is needed?"

Ductility generally is expressed in terms of percentage elongation and reduction in area as determined from standard tensile tests. Ratios of tensile yield to ultimate strength also give a measure of ductility. Specifications for certain alloy steels limit this ratio to a maximum of 0.70,[27] whereas for carbon steels it usually ranges from 0.50 to 0.60. It should be emphasized that all materials do not exhibit the same characteristics of ductility. Among the heat-treated aluminum alloys, for example, alloy 61S–T, with a ratio of tensile yield to ultimate strength of 0.85 and an elongation in 2 in. of 14%, may show better ductility as far as forming operations are concerned than alloy 17S–T, with a ratio of tensile yield to ultimate strength of 0.65 and an elongation of 20%. If reduction in area is used as the measure of ductility, however, rather than the ratio of tensile yield to ultimate strength, or elongation, a more consistent indication of the relative forming characteristics of these particular aluminum alloys is obtained.

Carbon steel apparently has such a margin of ductility beyond that required for most structural uses that there has been little need to attempt to establish a definite relation between this property and the behavior of structural members. Observations on the behavior of actual structures are of little help in this respect since the latter are not designed to function in a stress range where ductility is a significant factor. Few structural tests appear to have been made in which the effect of ductility was one of the principal variables considered. It has been shown by static tests on riveted joints of steel and aluminum alloys[28] that differences in elongations ranging from a minimum of 11% to a maximum of 39% (measured over gage lengths of four diameters) had no apparent effect upon structural behavior. The joint strengths were within a few per cent of predicted values, indicating that the needs for ductility to level off stress concentrations and to effect a uniform distribution of load between rivets were amply met.

The author points out that the welding of structural steels may produce stress concentrations that are detrimental to the fatigue strength of a member. No mention is made of the effect of welding upon ductility. Tests by Professor Wilson, with Messrs. Bruckner and McCrackin,[15] as reported in 1942, have shown, however, that elongation values for butt welded tensile specimens of low-alloy steels may be as low as 5% in 8 in., when fractures occur in the welds. The effect of this "local brittleness" upon shock resistance and fatigue strength would appear to be an important consideration, although the increasing use of welded steel construction might be interpreted to mean that this reduction in ductility is not a critical factor.

[27] "Specifications for Steel Railway Bridges," A.R.E.A., Pt. 3, Alloy Steels, 1938.

[28] "Riveted and Pin-Connected Joints of Steel and Aluminum Alloys," by Leon S. Moisseiff, E. C. Hartmann, and R. L. Moore, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1359.

Experience is needed, of course, to indicate to what extent ductility may be utilized in a structural material. The civil engineer, accustomed to thinking in terms of the ductility of carbon steel, will naturally have a different conception of this property, and of minimum structural requirements, than the aeronautical engineer, whose principal structural materials are alloy steels and nonferrous metals. The successful structural use, in aircraft, of metals having elongations of 10% to 14% in 2 in. (which is appreciably less than those generally prescribed for other types of structures) emphasizes the need for a better understanding of the functions of ductility with respect to structural behavior.

LEON S. MOISSEIFF,[29] M. AM. SOC. C. E.—The experience that engineers and metallurgists have had with structural members has brought to their minds in recent years an increasingly important problem. Professor Wilson deals with the information essential to this problem. He asks what physical properties of metals are desirable and may be required to assure the best behavior of structural members. The problem is not an outcome of theoretical considerations; it is a purely practical one. Based on his wide experience, Professor Wilson poses the problem on observations, engineering practice, and tests.

In the "Synopsis" of the paper the statement is made that "It is reasonable to infer that, if certain physical properties are prescribed, there must be some quite definite relation between these properties and the behavior of structural members." This suggests that the author doubts the correctness of the inference—and so do many engineers with him. It has been found in many cases that the physical properties prescribed in widely adopted specifications are insufficient to assure the desired behavior of structural members. As stated by Professor Wilson, many years of experience in fabricating and using structural carbon steel have proved that these specifications and the prescribed tests for the acceptance of the material have served well the requirements of the structures in operation. In fact, it should be emphasized that the specified physical properties of structural carbon steel and the acceptance tests for them have been developed by engineers during these many years of experience by closely following the behavior of the material, constituent members, and structures in use. Also, it should be kept in mind that commercial acceptance tests are limited by practical considerations. From the practical side it is important that such tests should be relatively simple and should consume little time. Acceptance tests have been standardized for fair comparisons and definite results and also to attain speed in testing.

Engineers early recognized that the strength of the material is the first requisite. The behavior of the material under action of load or strain also soon attracted the attention of the practical master mechanic—some kind of a bend test was used for metals long before scientific testing. In developing the standard tension test for strength, the phenomenon of ductility attracted attention and was made part of the tension test, largely because it was concomitant with it. (This is available with the tension test and consumes little additional time.) The observation and recording of the reduction of area also fall in line with the tension test. Should additional physical properties be specified, they will require separate tests which may be more time consuming.

---

[29] Cons. Engr., New York, N. Y. (Mr. Moisseiff died on September 3, 1943.)

It was very fortunate that, in the transition from wrought iron to steel, the structural carbon steel of the present time was developed. Its wide use for structures is largely due to its dependability and workability. Most of the latter is due to its high ductility. The high percentage of elongation of structural carbon steel is a result of its manufacture; it was not aimed for especially. Low-alloy and high-alloy steels, as well as lightweight metals, however, do not show such high elongation as structural carbon steel. This has brought up one of the questions of the new problem: How high an elongation does a metal require to meet the requirements of modern fabrication and erection of structures? The author discusses at length the several factors which demand from the metal an elongation through ductility that surpasses the elastic elongation. There are indications of a quantitative evaluation of these factors in the paper. It is highly desirable, however, to establish experimentally the percentage of elongation required in a given metal to meet, safely, the possible plastic deformations that may occur during fabrication, erection, and operation.

To study the effect of higher and lower ductility of metals and the effect of higher and lower ratios of yield strength to ultimate strength and the effect of the moduli of elasticity on distribution of stress, a series of tests of riveted and pin-connected joints was made.[28] Five metals—two steels and three aluminum alloys—having a fairly wide range of ductilities and ratios of yield strength to ultimate strength were included. All the joints tested behaved in a manner consistent with the basic assumptions of design and with the properties of the materials. Furthermore, the tests showed that the plastic yielding necessary to effect a uniform distribution of load among the rivets must be relatively small and that differences in ratios of yield strength to ultimate strength, elongation values, and moduli of elasticity were not significant factors as far as static ultimate strengths were concerned.

In these tests it was shown that the plastic yielding necessary to attain a uniform distribution of load in the riveted joints was relatively small. Tests on various structural parts in which stress-raising is expected may furnish information on the percentage of ductility required for practical purposes.

In discussing physical properties that affect the behavior of structural members, the writer thinks it is appropriate to mention some desirable physical properties which metallurgists may strive for.

One such property is the physical durability of the metal, its resistance to corrosion. In recent years a fraction of 1% of copper has been introduced to the chemical constituents in structural steels as protection against rust. There probably are other corrosion retarding agents which could be utilized economically. The assurance of a very low rusting quality would allow engineers to improve the design of structural members.

Another property of metals which is all important in the behavior of structures is their modulus of elasticity. It is amazing how the numerical value of the modulus remains practically unchanged for a given metal. It appears to be independent of the other physical properties and of the process of manufacture. Thus, rolled structural steel and high-strength stainless steel will show practically the same modulus as the cold-drawn bridge wire, which is nearly four times as strong as structural steel. Various grades of aluminum and duralumin have the same aluminum modulus; and other metals also have a specific value. This phenomenon is so striking that it arouses the curiosity of engineers. The satisfaction of this curiosity and raising the modulus of some metals would result in tremendous advantages of structural and economical value. These facts call for research of the highest kind. Whether the modulus of elasticity results from the forms of the crystals and their pattern in the metal and whether these could be modified by controlled processes affecting their formation is a problem of transcendental interest. Structural engineers need not be told that successful research in these problems will result in substantial gains.

FRED L. PLUMMER,[30] M. AM. SOC. C. E.—The importance of the ductility of structural steels is emphasized in this paper as necessary in order to avoid possible failures due to: Fabrication and erection operations; stress concentrations caused by inaccurate fabrication, irregularities, welding heat or forced deformations; or excessive stresses caused by shock loads. J. A. Van den Broek and Hardy Cross, Members, Am. Soc. C. E., and others also have discussed the capacity of ductile metals to undergo relatively large deformations when stressed to the yield point, thereby modifying the distribution of stresses and possibly increasing the safe load-carrying capacity of the structure.

The ductility, to which these authors refer, is measured usually in connection with tension tests in which uniaxial stress is applied at room temperature and in small increments separated by definite time intervals or at a relatively slow but uniform rate. Thus, the reported values do not reflect the possible effect of temperature, rate of propagation of stress, or biaxial or triaxial stress distributions. Service failures of steel structures almost invariably show none of the deformations which are characteristic of failures in the tension tests. This indicates that ductility has failed to perform the functions suggested by the author, at least in these specific cases.

Professor Wilson refers to the structural steel covered by specification A7.[2] Many structural shapes are rolled from steel meeting this specification. Steel plates used for structural work often are selected to meet specifications A10 or A70. Such steel plates, ordered from different manufacturers and meeting all requirements of these specifications, may consist of "rimmed steel," "killed steel," or "semi-killed steel." However, metallurgists state that the resistance of these steels at low temperatures to impact forces and their susceptibility to age embrittlement following plastic deformation may be quite different.

---

[30] Chf. Research Engr., Hammond Iron Works, Warren, Pa.

Steel plate structures frequently consist of plates that have been bent or dished into curved shapes by rolling or forming. Thus such plates are subjected to more "cold working" than most of the structural shapes used in bridges and buildings although these members sometimes receive similar treatment. In steel plate structures the principal elements of the structure are subjected frequently to biaxial stresses of approximately equal intensities whereas the principal members of bridge and building structures normally resist only uniaxial stresses.

The writer would appreciate a statement from the author indicating whether he considers safe the use of steel plates meeting the requirements of specification A70 in a code-designed structure: (1) For which the plates will be formed cold to a dished shape (age embrittlement following plastic deformation); (2) in which biaxial stress conditions will exist throughout most of the structure (partial loss of effective ductility); (3) which will be subjected to atmospheric temperature variations in an area when for short periods the temperature will fall below 0° F (lower resistance to impact forces); (4) of which the various plates will be assembled by carefully controlled welding processes (stress concentrations due to welding heat); and (5) which, during such a period of low temperature, might be subjected to an impact force while resisting the normal design loads (speed-of-stress propagation). If the author does not consider the specifications adequate, in what way would he suggest that they be modified so as to insure the production of a steel that would meet the foregoing requirements adequately?

Structural engineers are widening continuously the scope of their activities. This applies to the types of structures which they design and to the kinds of metals to be used in such structures. Not many years ago the typical structural steel designer was concerned primarily with the use of one material, one method of fabrication, and the proper proportioning of members subjected to bending forces or to a direct thrust or pull, together with relatively simple "connections." Now he may choose from a wide variety of alloy steels and nonferrous metals in proportioning the parts of complicated continuous structures, including parts such as "skin structures" whose strength depends upon their elastic stability. He may connect the parts of his structure with rivets or by welding. It is only natural, but perhaps fatal, to try to apply old standards, tried procedures, and tested ideas to new materials used in new types of structures. Professor Wilson serves all engineers in outlining some of the problems and indicating a few about which additional information is needed.

A. A. Eremin,[31] Assoc. M. Am. Soc. C. E.—The physical properties of steels affecting the design of structures may be determined from diagrams expressing stress-strain relations for tests on steel. Sufficient data are not yet available to draw the diagrams for various types and shapes. However, considering the similarity of some characteristic features of steels, the diagrams available at present are sufficient to determine the approximate influence of the physical properties of steels on the behavior of structures. Interesting diagrams of this stress-strain relation have been presented by S. Timoshenko.[32]

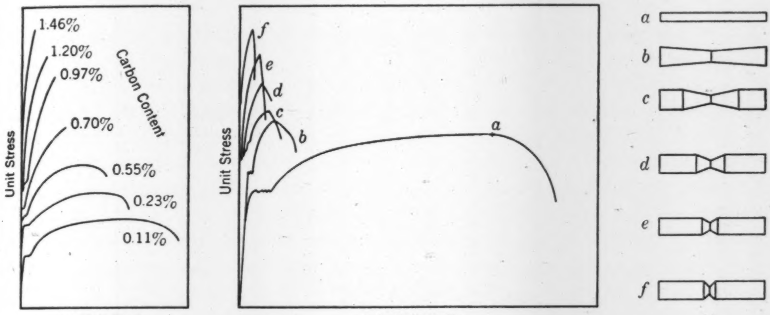
[31] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[32] "Strength of Materials," by S. Timoshenko, Pt. II, 2d Ed., Van Nostrand, p. 553.

In Fig. 2(*a*) stress-strain diagrams for steels with various carbon content are shown. The ductility is decreased with an increase of the carbon content. The alloy steels are characterized by a carbon content varying from 0.25% to 0.50%. Therefore, Fig. 2(*a*) makes it possible to determine an approximate relation between the plastic flow of alloy steels and A7 steel. These curves prove the author's statement that, where plastic flow is desirable, the low-alloy steels or A7 steel should be used. Fig. 2(*b*)[33] shows relative stress-strain diagrams for steel members with reduced mid-sections such as those in Fig. 2(*c*). Members in which notches are cut, or members with variable cross section, lose their ductility although their ultimate strengths are increased.



(*a*) Unit Strain (*b*) Unit Strain (*c*)

Fig. 2.—Relative Stress-Strain Diagrams for Steel

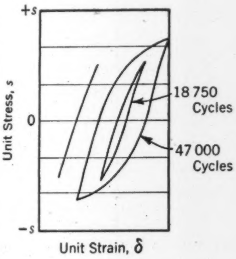


Fig. 3

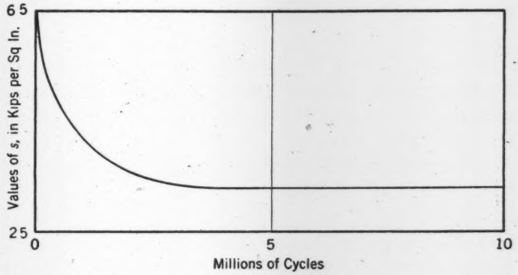

Fig. 4

The capability of steel to harden under repeated loading is shown in Fig. 3. It is obvious that the alternate loading in a member may raise its yield point and produce a stiffening effect.

In conclusion (1), the author states that structural members should be designed for known forces and then checked against fatigue failure. From Fig. 4 it is obvious that the fatigue effect on stress in the members may be estimated and considered as a special type of loading. Therefore, it is possible to design the structure for a combined loading including the fatigue effect.

---

[33] *Der Stahlbau*, June 19, 1936, p. 109.

In conclusion (2), Professor Wilson states that the plastic deformation permits the redistribution of uneven localized stresses. From Fig. 2 it is evident that the plastic deformation at the reduced sections, where the localized stresses occur, is considerably reduced. Therefore, its effect on the redistribution of stresses is negligible.

Wilbur M. Wilson,[34] M. Am. Soc. C. E.—The action of a composite plate girder with silicon-steel flanges and a carbon-steel web has been presented in the discussion. The problem, which is within the scope of the paper, is one of considerable importance and would seem to justify a more detailed consideration than has been given. The following discussion is based upon the premise that a member with given geometrical characteristics buckles at a certain average critical strain rather than at a definite average critical stress. Actually, the buckling strength depends upon both stress and strain, but, for a stress range in which Hooke's law does not apply, the average strain at which buckling begins is much more nearly constant than the average stress. The discussion is based upon the further premise that the carbon-steel web of the composite girder will have the same thickness as the silicon-steel web of the all-silicon girder which otherwise might have been used.

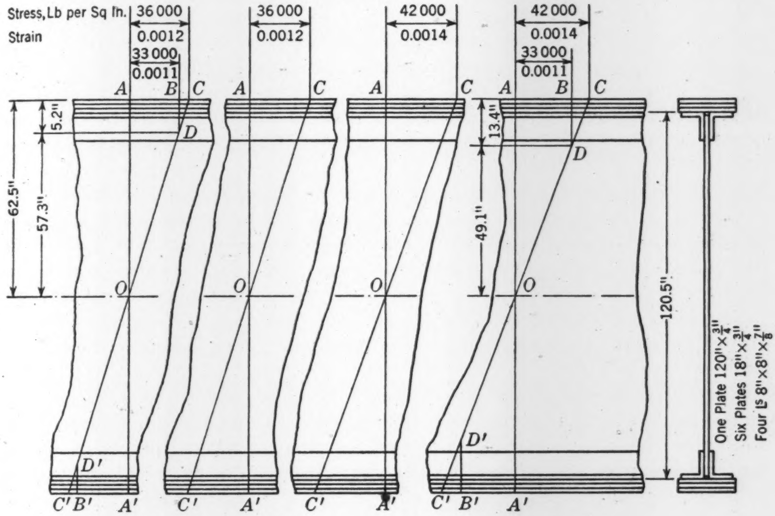
The distribution of the stress and strain on a transverse section of a plate girder is shown by the diagrams of Fig. 5. To simplify the problem, the computations have been made on the basis of the gross section so that, for a girder symmetrical about the center line, the tensile and compressive stresses are equal. The girder is composed of a 120-in. by $\frac{3}{4}$-in. web, four 8-in. by 8-in. by $\frac{7}{8}$-in. angles, and six 18-in. by $\frac{3}{4}$-in. cover plates. Figs. 5(*a*) and 5(*b*) are for a section at which the maximum stress is 36,000 lb per sq in.; this is eight tenths of the yield point of silicon steel and corresponds to a capacity rating.

The area OACOC′A′O in Fig. 5(*b*) represents both the stress and the strain on a section of an all-silicon girder. The yield point has not been exceeded, and the stress is proportional to the strain over the entire section. The resisting moment corresponding to a maximum stress of 36,000 lb per sq in., based upon the gross section and computed by the moment-of-inertia method, is 28,373,400 ft-lb.

The area OACOC′A′O in Fig. 5(*a*) represents the strain on a section of a composite girder with a carbon-steel web and silicon-steel flanges. The same area also represents the stress on the silicon part of the girder, but the stress on the carbon web is represented by the area OABDOD′B′A′O. The resisting moment corresponding to a maximum stress of 36,000 lb per sq in., based upon the gross section and computed by the moment-of-inertia method, is 28,357,800 ft-lb, which is 99.94% of the resisting moment of the all-silicon girder. Although a small part of the carbon web between the angles is stressed beyond the yield point, the maximum strain in the web due to a moment of 28,373,400 ft-lb (the moment-resisting capacity of the all-silicon girder) is only 0.06% greater for the composite girder than it is for the all-silicon girder. Therefore, the composite girder with carbon web and silicon flanges would appear to have as great a moment-resisting capacity as the all-silicon girder when the maximum stress is 36,000 lb per sq in. Furthermore, there would seem to be no more danger of buckling and no more tendency for the rivets to loosen for the composite girder than for the all-silicon girder since both tendencies to fail are functions of the strain and there is no significant difference between the maximum strains for the two types of girders.

---

[34] Research Prof., Structural Eng., Civ. Eng. Dept., Univ. of Illinois, Urbana, Ill.



(a) SILICON FLANGE CARBON WEB (b) ALL SILICON GIRDER (c) ALL SILICON GIRDER (d) SILICON FLANGE CARBON WEB

FIG. 5.—STRESS-STRAIN RELATIONS FOR VARIOUS GIRDERS

Consider now the conditions when the girder is subjected to an accidental maximum flexural stress of 42,000 lb per sq in.—a stress greater than any that would be considered in either the design or the rating of a bridge. The resulting stress and strain are shown in Fig. 5(*c*) for the all-silicon girder and in Fig. 5(*d*) for the composite girder. Since no part of the all-silicon girder is stressed beyond the yield point, the strain and stress are both represented by OACOC′A′O; for the composite girder, the strain is represented by OACOC′A′O, but the stress in the web is represented by OABDOD′B′A′O. The resisting moment corresponding to a maximum stress of 42,000 lb per sq in. is 33,102,300 ft-lb for the all-silicon girder and 32,881,300 ft-lb for the composite girder, the latter being 99.15% of the former. Although this extreme increase in stress (to 42,000 lb per sq in.) has increased the part of the carbon web that is stressed to the yield point, the maximum strain in the web due to a moment of 33,102,300 ft-lb (the moment-resisting capacity of the all-silicon girder) is only 0.85% greater for the composite girder than it is for the all-silicon girder. Inasmuch as the tendency to buckle and the tendency to loosen rivets are both functions of the strain, these tendencies to fail are not significantly different for the two kinds of girders.

The statement has been made in the discussions that the writer did not answer the question which he raised in the last sentence of the "Synopsis." This question restated is: "Are there characteristics of the material that should be considered which are not now determined in acceptance tests?" The writer listed or implied in the "Summary and Conclusions" some characteristics of structural steels which are not now generally familiar to structural engineers but which he believes should become known before the steels are subjected to the services and fabrication methods that are becoming more common. This is particularly true for the newer steels, as stated by Mr. Jones.

Mr. Kinzel expresses the belief that the writer has been unduly conservative in his attitude toward low-alloy structural steels with special reference to the possible injurious effects of welding and flame-cutting. Mr. Kinzel is a metallurgist and is accustomed to addressing metallurgists. The writer is a structural engineer with a limited knowledge of metallurgy and is accustomed to addressing other structural engineers, many of whom likewise have a limited knowledge of metallurgy. Warnings to an expert in any field may be uncalled for whereas warnings to a novice in the same field may be entirely in order. Many structural engineers are novices in the field of metallurgy.

A conservative engineer is naturally reluctant to use steels that can be embrittled during fabrication by deviations from prescribed procedure. His problem is to be sure that, in the confusion of shop fabrication and field erection, the proper procedure is always followed. What is most to be feared is incidental welding and flame-cutting not called for on the drawing and done without the knowledge of the engineer and by other than approved procedure. The writer agrees with Mr. Kinzel that low-alloy steels can be flame-cut and welded satisfactorily when the proper procedure is followed, but he also believes that a word of caution intended to insure that the proper procedure is followed is in order. The warnings in the paper were to emphasize the need for caution and not to discourage the use of welding and flame-cutting or the use of low-alloy steels.

Mr. Kinzel's reference to the undesirable features of riveted structural members is quite in order. There are locked-up stresses in structures fabricated by riveting. Punching and riveting do injure both carbon and low-alloy structural steels. Riveted members are particularly susceptible to fatigue failure as the writer's own tests indicate.[35]

With regard to embrittlement subsequent to plastic deformation, Mr. Kinzel states in the third paragraph of his discussion:

> "* * * It has been well demonstrated that fully killed steels—either the silicon or aluminum types—are not subject to this phenomenon. This fact removes a very large part of steel from consideration. Most of the low-alloy steel is fully killed. As to those steels which are not fully killed and may or may not exhibit strain aging, it should be stated that forming, punching, drilling, and similar processes used in general construction, and particularly in preparation for riveting, produce more than sufficient strain to cause the phenomenon, and such strain is set up at points of high stress concentration. Nevertheless, as Professor Wilson well demonstrates, experience justifies the conclusion that such steels are suitable for structural

---

[35] *Bulletin No. 302*, Univ. of Illinois Eng. Experiment Station, Urbana, 1938, p. 103.

> purposes after fabrication by riveting. Although one must be in accord with any plea for more information on any subject, it would seem that there is no need for the implication that further information on strain-age characteristics is needed vitally for immediate engineering use."

Mr. Kinzel does not include any mention of rimmed steels. Some rimmed steels are susceptible to embrittlement subsequent to plastic deformation. Structural specifications do not prohibit the use of rimmed steel. Unquestionably rimmed steel is used. One reason this mysterious (to the structural engineer) phenomenon should be investigated is that there have been occasional brittle failures of structural members in service for which there has been no acceptable explanation. Some years ago the writer tested fifteen wide plates without joints[36] (20 in. to 40 in. wide) to compare the unit strength of the wide plates with the unit strength of control specimens cut from the same parent plates. Of three supposedly identical specimens 20 in. wide, the elongation in 8 in. was 35.1% for one and 23.5% for another. The third broke with a brittle fracture with practically no elongation. The structural engineer rightly wants to know why these brittle fractures occasionally occur.

Mr. Kinzel asks how much experience would be necessary to determine whether or not any particular method of fabrication was susceptible to fatigue. Fatigue failures may occur after a few thousands of cycles or after a few millions of cycles. Except for temporary bridges, designs should be based upon a long life. Fatigue failures have developed in carbon-steel members with bad stress raisers after many years of service. If a railroad bridge is designed for 50 years of service, the fact that the members were intact after 30 years of service would not be proof that it was properly designed against fatigue.

In discussing the relative fatigue strength of low-alloy and carbon-steel structural members, Mr. Kinzel states:

> "* * * it is likewise true that, given reasonable surface conditions and geometry, fatigue strength does increase with the static strength in most instances."

Unfortunately, riveted structural members and welded structural members, except members with butt welds with the reinforcement ground flush, do not have "reasonable surface conditions" as judged by their ability to resist fatigue.

As a result of comparative fatigue tests of riveted joints in carbon, silicon, and nickel steels,[35] the Committee on Iron and Steel Structures of the American Railway Engineering Association revised its specifications for railway bridges, reducing the allowable stress in silicon-steel and nickel-steel members subjected to fatigue.[37] The present requirements may be somewhat more drastic than necessary but have been adopted until such time as more information is available.

Mr. Kinzel takes exception to the many cautions relative to low-alloy steels, flame-cutting, and welding. Not all of these have been answered in particular because, as stated previously, the differences between Mr. Kinzel and the writer seem to be in degree only and are due to differences in background and viewpoint. Although the writer believes that his cautions to structural engineers are in order, he believes that Mr. Kinzel's viewpoint is necessary to complete the picture and welcomes the discussion in which it has been presented.

---

[36] *Bulletin No. 239*, Univ. of Illinois Eng. Experiment Station, Urbana, p. 11.

[37] "Specifications for Steel Railway Bridges," A.R.E.A., 1942, Pt. 3, Alloy Steels, paragraph 9 of the Foreword.

The writer was quite gratified to note that Messrs. Moisseiff and Moore recognized the implication in the statement in the "Synopsis"—

> "It is reasonable to infer that, if certain physical properties are prescribed, there must be some quite definite relation between these properties and the behavior of structural members."

This statement does contain the implication that all of the physical properties prescribed may not be needed, at least not for all structural members. Specifications of a material are usually a compromise between what the engineer thinks he wants and what the manufacturer can produce at a reasonable cost. The structural engineer has been spoiled by the high ductility combined with a fair strength that is obtained in carbon structural steel, one of the cheapest structural materials available. When he began to seek a material of higher strength or of lighter weight, he was reluctant to accept a lower ductility. Conservativeness and inertia probably are at least partly responsible for the demand for high ductility in the high-strength steels.

The objective is shock-absorbing capacity of the structural member rather than ductility of the material; and, as stated in the paper, shock-absorbing capacity depends upon the geometrical characteristics of the member as well as upon the physical properties of the material. Also, as cited in the paper, there are structural members fabricated of steels of low ductility that have a greater shock-absorbing capacity than the usual type of member fabricated of A.S.T.M.-A7 steel. Yet geometrical characteristics of the member have few restrictions in the specifications, and, in so far as the literature indicates, have been given little consideration by the profession. Usually where the final objective is a function of two factors, as is true for the shock-absorbing capacity of a structural member, the characteristics of both factors are considered. Investigations to determine the interrelations of the ductility of the material and the geometrical characteristics of the member are greatly needed. A few exploratory tests have been reported.[38] Inasmuch as ductility does not affect the shock-absorbing capacity except as yield-point stresses occur, and the latter generally occur only under accidental loads, high-speed tension tests which simulate accidental shocks are needed. Also, because the geometrical characteristics are equally as important as ductility, tests on small specimens of constant cross section and smooth surface would be of little value in evaluating the behavior of a structural member. What would seem to be needed are tests of specimens with the geometrical characteristics of structural members and as large as it is possible to test.

Mr. Plummer asks the writer whether or not he considered it safe to use A.S.T.M.-A70 steel under certain conditions which he prescribed involving: Age embrittlement subsequent to plastic flow, multiaxial stress conditions, low temperatures, welding, and shock. What a collection of unsolved problems! If the writer had authoritative answers to all of the problems involved in Mr.

---

[38] *Journal*, Am. Welding Soc., July, 1943, p. 317-s.

Plummer's question, he would not have written this paper. As stated by Mr. Plummer, the changes that are taking place in structural engineering practice are so great that it is not safe to assume that old practices necessarily apply to new conditions. Moreover, the impatience of modern times makes it necessary to learn in the laboratory in a few years what, in the past, was learned to a considerable extent by experience over a long period of years.

The last paragraph of Mr. Eremin's discussion reads as follows:

> "In conclusion (2), Professor Wilson states that the plastic deformation permits the redistribution of uneven localized stresses. From Fig. 2, it is evident that the plastic deformation at the reduced sections, where the localized stresses occur, is considerably reduced. Therefore, its effect on the redistribution of stresses is negligible."

This is the action which the writer had in mind in the discussion of combined deformation stresses and load stress in which he stated (see heading, "Why Is Ductility Necessary: Errors in Workmanship (Item (3))"),

> "Likewise, a high, combined, load-and-deformation stress cannot be accepted in a tension member that has a reduced section at a point of maximum stress."

In discussing fatigue, Mr. Eremin states,

> "From Fig. 4 it is obvious that the fatigue effect on stress in the members may be estimated and considered as a special type of loading. Therefore, it is possible to design the structure for a combined loading including the fatigue effect."

It is the opinion of the writer that there are two distinct steps in the design of structural members subjected to fatigue. The allowable static stress has one value, which is constant for a given material. The allowable fatigue stress usually differs from the allowable static stress. Moreover, it is different for different types of members fabricated of the same steel and is different for different members in the same bridge due to the fact that some members are subjected to more stress cycles than other members of the same bridge. (Hip verticals are more susceptible to fatigue than end posts.) Likewise, the maximum stress for which the member is designed would be different in designing for static load than it would be in designing for fatigue. In designing a member for static load, the maximum possible stress that could be produced by the design load should be used. In designing for fatigue, only the stress that is likely to occur frequently should be considered. To illustrate, consider a two-truss double-track bridge. There is a possibility that the two tracks will be loaded simultaneously so, in designing for static loads, both tracks should be considered loaded; but, because for most bridges the simultaneous loading of both tracks would occur at very infrequent intervals, only one track should be considered loaded in checking for fatigue. Of course, the empirical methods of designing for reversed stresses now in use do not take into account these possibilities, but it should be borne in mind that these empirical rules were written when there was relatively little known about the fatigue strength of structural members, as distinguished from the fatigue strength of small machined specimens. Tests have recently been made to determine the fatigue strength of structural members,[39] which probably will result in some revision of the paragraph in the specifications which controls the design of structural members subjected to fatigue. Curves like the one shown in Fig. 4 are needed for the types of members fabricated of various materials. The data for some of the curves are available, but a large amount of testing remains to be done.

The best method of designing structural members subjected to reversals and repetitions of stress has yet to be determined. The number of structural members seriously affected by fatigue is relatively small. The design load is not the same for fatigue as for static stresses. The ratio of the allowable fatigue to allowable static stress is not the same for low alloys as for carbon steel; it is not the same for all types of members; and it is not the same for all members of the same structure.[40] It would seem to the writer, therefore, that the best way to design is to proportion the members for the static loads (dead load, live load, and impact), and then check those members subjected to repeated or reversed loads for the possibility of a fatigue failure.

The writer believes that the paper, together with the discussions which it has evoked, has served a useful purpose in that it has:

1. Emphasized the manner in which the ductility of the material redistributes the stress when static stresses reach the yield point in regions of stress concentration;
2. Pointed out conditions under which yield-point stresses are and are not dangerous;
3. Called attention to the fact that the final aim sought, large shock-absorbing capacity of a member, depends upon the geometrical characteristics of the member as well as upon the physical properties of the material;
4. Indicated the possibilities of developing new types of structural members with geometrical characteristics which will result in a large shock-absorbing capacity even though the material has less ductility than has generally been considered necessary; and
5. Enumerated research projects which might lessen the risk that would otherwise accompany a too rapid adoption of new materials and new fabricating processes.

PRIMARY RÔLE OF METEOROLOGY IN FLOOD FLOW ESTIMATING

BY MERRILL BERNARD,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. EDGAR DOW GILMAN, CLARENCE S. JARVIS, IVAN E. HOUK, W. G. HOYT, L. R. BEARD, ROBERT E. KENNEDY, L. K. SHERMAN, C. H. EIFFERT, GAIL A. HATHAWAY, L. STANDISH HALL, AND MERRILL BERNARD.

SYNOPSIS

This paper undertakes to report on certain progressive developments in applied hydrology, now a recognized field of engineering, and the science of meteorology, heretofore primarily associated with the prediction of weather and with the generalized influences of weather on the climatic régimes of a region.

Inadequacy in the quality, extent, and length of precipitation records has given incentive and justification to the development of more rational design techniques so that the flood to be accommodated by a structure may bear a direct relation to type and magnitude of the storm that will ultimately produce it.

Precipitation data for approximately 350 of the nearly 1,300 storms of record have been reviewed, the analysis beginning with the rainfall observers' notes. Of this number about 150 are presented in the paper, the tabulations including representative time-area-depth values.

The principal meteorological elements are defined. The distribution of moisture in the atmosphere and the dynamic action between air masses are discussed in sufficient detail to give basic understanding of the mechanism of storms.

Modern methods of water control and use have demanded a means for quantitative expression of the physical upper limits of storm rainfall. Efforts to meet this need are described, and although the studies which are the basis for this paper have been successful in achieving this end, they have also disclosed weaknesses in long-established techniques, inadequacies in quality and the extent of hydrometeorological data, and the need to readjust common concepts of flood-storm relationships.

It is the purpose of this paper to report on these relative successes and failures.

NOTE.—Published in January, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was published in *Proceedings*.

THE HYDROLOGIC CYCLE FUNCTIONALIZED

The march of events that marks the progress of an elemental particle of water from the sea surface into the atmosphere, to the land, and back to the sea is known as the hydrologic cycle. In its passage two major influences are exerted—heat and the gravitational pull of the earth.

FIG. 1.—THE HYDROLOGIC CYCLE FUNCTIONALIZED

Heat emanating from the sun is absorbed by the earth's surface and radiated back into the masses of free air moving over this surface. Heat then becomes the basic cause of turbulence in the air layers coming into contact with ground, vegetal, and water surfaces. Thus, through convectional displacement, repeated opportunity is provided for the absorption and removal of evaporated moisture.

The hydrologic cycle is not completely represented in the usually accepted sequence—from sea to land to sea. A particle of water evaporated from an ocean surface may be deposited very quickly at sea as part of a raindrop and so may never reach the land. Another particle may be taken into an air mass that moves to and over an extensive land area and out to sea again before meeting the influences necessary to convert it from vapor to liquid. Still another representative element in the train of moving water vapor may be deposited as rain or snow on the land, retaken into the atmosphere by evaporation, and transported back to the sea by air.

Much of the transitional water of the earth follows the more typical cycle that deposits the raindrop on the land surface, where it joins the runoff in overland flow, and enters a stream that ultimately flows into the sea. A modified cycle is that in which the raindrop enters the ground and reaches the stream later, through orifices below the flow line of its channel, whereas still another drop may continue downward under the action of gravity to some deep ground-water reservoir from which it may ultimately reach a stream or percolate into the sea.

If all the moisture in the atmosphere were suddenly precipitated, there would be only enough to produce an average depth of about 1 in. of water over the total surface of the earth. What, then, accounts for the fact that rainfalls of more than 20 in. in 24 hr are experienced in many parts of the world? The answer is given by the meteorologist who observes and analyzes the factors known to bring about the convergence of vast air masses heavily burdened with moisture.

Fig. 1 has been prepared to show how the meteorologic, hydrologic, and hydraulic phases of the water cycle are related functionally as well as physically. Inescapable overlapping of interest is apparent and the need for coordinated effort becomes obvious.

It is believed that meteorology must play an increasingly important rôle in engineering planning. Although the science is not truly "exact," the meteorologist, nevertheless, deals with a medium for which well-established physical laws are known. His greatest limitation lies in the impossibility of sampling the vast extent of the atmosphere in a manner which even approaches statistical exactness.

INADEQUACY OF FLOOD DISCHARGE RECORDS

It would have been difficult before May, 1935, to convince the residents of "Wakefield, Kans., that the discharge in the Republican River could have greatly exceeded 70,000 cu ft per sec. The maximum flood flow of record had increased from 37,500 to 47,500 cu ft per sec in 1903, and to 70,000 cu ft per sec in 1915, but for the next twenty years the river failed to reach or exceed the 1915 crest discharge. In May, 1935, the Republic River Basin was visited by a storm which produced a flood peak estimated at 180,000 cu ft per sec. The prevailing maximum-flood discharge, as it progressed throughout

the period of record at Wakefield, and a similar relation between increasing record length and maximum-flood discharge at Pueblo, Colo., on the Arkansas River, is shown in Fig. 2.

The City of Wakefield will have established 100 years of record of stream flow in the year 1995. As this record progresses the prevailing maximum flood will approach the asymptotic limit represented by a flood which will result from the most critical combination of maximum-storm rainfall, snowmelt contribution, and minimum losses to storm runoff. The insecurity in estimating maximum-flood discharge by extrapolating the curves in Fig. 2 accounts largely for the rationalized design methods developed by the Engineer Department of the Corps of Engineers, and others bearing a responsibility for flood-control design.

INADEQUACY OF PRECIPITATION RECORDS

A number of the larger cities in the United States have records covering approximately 100 years. These records are valuable in statistical studies relating rainfall intensity to duration, but are of limited value in problems involving the areal distribution of flood-producing rainfall over a basin. Only a few of the historical storms, that of August 5, 1843, in New Jersey and eastern Pennsylvania being an example, are sufficiently represented by data to permit the plotting of isohyetal maps. In the main, it has been necessary to make best use of the record period beginning about 1892, a conclusion also reached by the Miami Conservancy District in its classic work, "Storm Rainfall of Eastern United States" (1).[2]

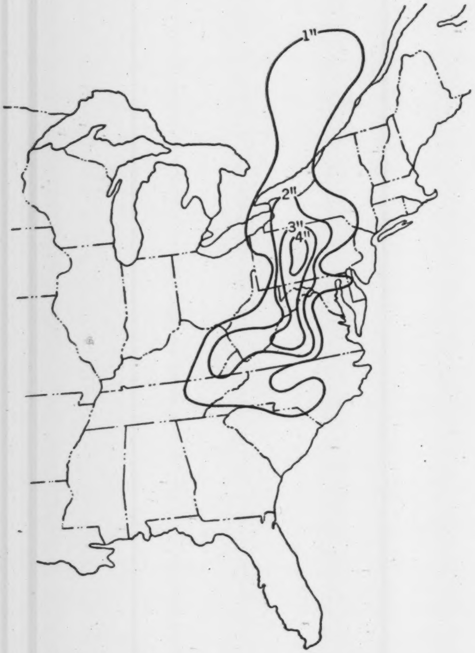

FIG. 5.—ISOHYETAL MAP FOR THE 24-HR PERIOD ENDING 8:00 A.M. (E.S.T.), MARCH 18, 1936

This paper will not undertake to review the development of flood-control planning. It is sufficient to state that early attempts in utilizing recorded storm rainfall as a guide to the measure of future storms failed in answering the questions: "Could this storm, having occurred here as recorded, been greater in intensity, duration and extent?" or, "Could this storm, having occurred here, be considered as representative of one which will ultimately center over a particular basin located outside its limits?" The meteorologist, whose field embraces the causes of precipitation, has been called upon to consider these questions.

---

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix 1).

THE STORM AS THE DESIGN UNIT

Storm rainfall can be converted into flood flow in a rational and realistic manner. All of these rational methods require that rainfall be expressed in terms of average depth occurring within a fixed period of time, distributed over an area of known dimensions and pattern. Only rainfall recorded concurrently can become the basis for such analysis, a requirement seldom fulfilled by the older records which often fail to disclose the actual period during which the rain fell. It can be seen that if stations "A" and "B" are sufficiently close they will produce practically identical records of rainfall. As they are separated by increasingly greater distances the record at "B" becomes less and less dependent upon that at "A" until the records are no longer related and, therefore, cannot be combined even when statistically identical (4).

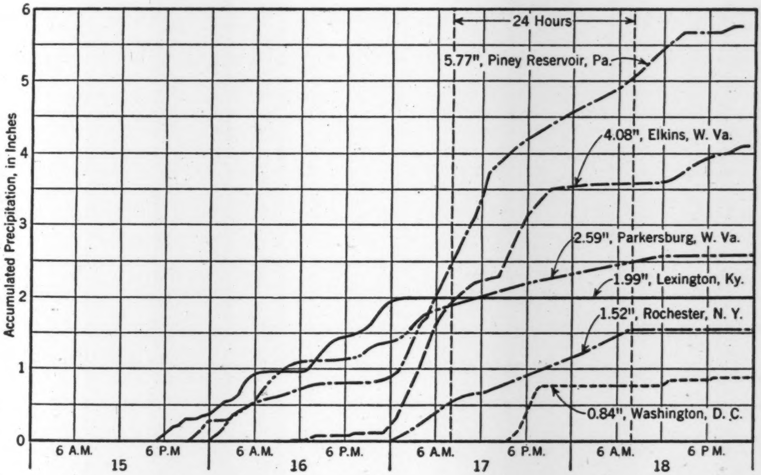

FIG. 6.—MASS CURVES OF RAINFALL FOR MARCH, 1936

Thus far the writer has treated only the "hydrologic storm," shown graphically as an isohyetal map and usually limited in total extent to areas less than 200,000 sq miles. The meteorologist, quite naturally, is interested in the hydrologic storm as it expresses the results of his analysis. However, he has been more directly interested in what will be referred to in this paper as the "meteorologic storm," a three-dimensional phenomenon of considerably greater extent than the hydrologic, or "rain" storm. His medium is the earth's atmospheric envelope—the field of action being the greater part of the northern

hemisphere. He has classified the interacting air masses on the basis of their heat and moisture properties, and has determined the manner in which one will oppose or yield to another. This generalized concept of cause and effect is illustrated in Figs. 3 to 6, in which the meteorologic storm represented by synoptic surface weather maps (Fig. 3) and isentropic charts (Fig. 4) is compared with the hydrologic storm expressed as an isohyetal map (Fig. 5) and mass curves of rainfall at selected points throughout the storm area (Fig. 6).

Beginning, then, with a general atmospheric disturbance of nation-wide proportions, the engineer-hydrologist moves progressively through the extensive area of general precipitation to the concentrations of rainfall of basin-wide extent. Here he assumes the responsibility for routing flood water over the ground as surface runoff and through the channel system as the flood wave.

HISTORICAL BACKGROUND OF STORM RECORDS

"Storm Rainfall of Eastern United States" (1) by the Miami Conservancy District, continues to be outstanding as an example of organized storm data. This excellent compendium, however, does not provide the details essential to the use of more recently developed techniques for storm analysis.

In 1937, when cooperative studies were begun by the Corps of Engineers, the U. S. Department of Agriculture, and by the Weather Bureau in the U. S. Department of Commerce, it was necessary to organize the precipitation data within individual storms. Since the greater number of records were based on observations made with the nonrecording rain gage, it became a major problem to identify the period within which the rain actually fell. The observers' notes in the manuscript records would occasionally indicate the time of beginning and ending of rainfall, but the records of the comparatively few recording gages supplemented by a meteorological analysis of the synoptic weather maps for the period provided the means for making the most accurate distribution of cumulative rainfall depth throughout the duration of the storm.

Of the approximately 1,300 storms of record, about 350 have been analyzed in varying degree by the field offices of the Corps of Engineers and the Hydrometeorological Section of the Weather Bureau. Of this number 150 have been listed in Table 1. In addition to the generalized information giving the date and location of the storm, area-duration-depth values are included.

General Classification of the Principal Storm Types

The following classifications describe the basic actions which produce storm rainfall and, either singly or in combination, can be used to explain heavy rainfall in almost any part of the world. The primary requisites for intense rainfall are cyclonic convergent flow and a potential source of warm moist air. The addition of a lifting mechanism, such as a mountain barrier, or a wedge of cold air, enhances the opportunity for intense rainfall.

Type 1. Quasi-Stationary Front with Active Minor Waves.—A cold front that becomes quasi-stationary with sharp temperature and moisture contrasts between the air masses preceding and following the front, thus resulting in the development of active minor waves along the front.

Type 2. Rapidly Developing Waves Along a Cold Front.—Waves that develop rapidly into major cyclonic systems under favorable meteorological conditions.

Type 3. Major Occluded Cyclonic Systems.—Cyclones which, under favorable temperature and moisture conditions, develop into deep intense systems and cause cold polar air to sweep entirely around the system, thus cutting off the source of warm moist air and occluding the warm sector.

Type 4. Tropical Cyclones.—Storms of tropical origin which move inland, bringing with them unusual quantities of moisture to be precipitated as the storm slowly dissipates.

Type 5. Local or Frontal Thunderstorms.—

Local Thunderstorms.—Storms within an air mass resulting from convective overturning due to convergence, heating, or orographic lifting of moist, unstable air, but not associated with frontal activity.

Frontal Thunderstorms.—Storms produced by releasing the convective energy in moist, unstable, tropical air through frontal lifting.

Type 6. Moist Air Flow Up Mountain Slopes.—Storms resulting from steep pressure gradients which cause moist, unstable air to flow up mountain slopes.

A glossary of meteorological terms is presented as Appendix 2.

Regions of Meteorological Homogeneity

The mean annual isohyetal map for the United States shows the rainfall progressively decreasing from the seacoasts inland, indicating that its distance and direction from the source of moisture are important influences on the amount and duration of rainfall for a locality. Parts of the country having marked departures in annual rainfall are usually regions of rugged topography—surface irregularities exercising an almost independent influence on rainfall. Differences in annual rainfall between regions of similar physiographic characteristics and moisture accessibility confirm the opinion that still other factors help to determine a rainfall régime.

Since there are no distinct boundaries of regions with records of consistent rainfall experience, it must be concluded that any combination of all factors causing rainfall is transitional, and regions of meteorological homogeneity can be outlined only after certain tolerances have been accepted. It is obvious that such regions, under any definition, must vary widely in extent. Great areas can be embraced within prescribed limits in the central third of the United States, whereas it may be impossible to assign boundaries of homogeneity to areas of appreciable extent in the quite rugged humid southeastern quarter of the country.

A region of meteorological homogeneity is defined as one in which all points will have the same, or reasonably similar, records of rainfall intensity and duration at the end of a significant period; or, it may be stated that a storm entering such a region can center over any point with equal probability.

Studies to date have not been sufficiently extensive to allow the exact delineation of all meteorologically homogeneous regions throughout the United States. A tentative subdivision, however, can be made in the 21 areas defined below:

Area	Region
1	Western side of the Pacific Coast Ranges
2	The lee side of the Coast Ranges
3	The Great Central Valley, California
4	The western side of the Cascades
5	The eastern half of Washington and Oregon
6	The plateau region of Utah, with emphasis on the local topographic features
7	Southern Arizona and California
8	The western slope of the Rockies
9	The eastern slope of the Rockies
10	Northeast Arizona and northwest New Mexico
11	Eastern New Mexico and extreme west Texas
12	Western Oklahoma, Kansas, and Nebraska
13	Dakotas and eastern Montana
14	Minnesota and northern Wisconsin
15	Central Mississippi Valley
16	Upper Ohio Valley
17	Western slope of the Appalachians
18	Northeastern States
19	Middle Atlantic Coast
20	Eastern Gulf States
21	Western Gulf States

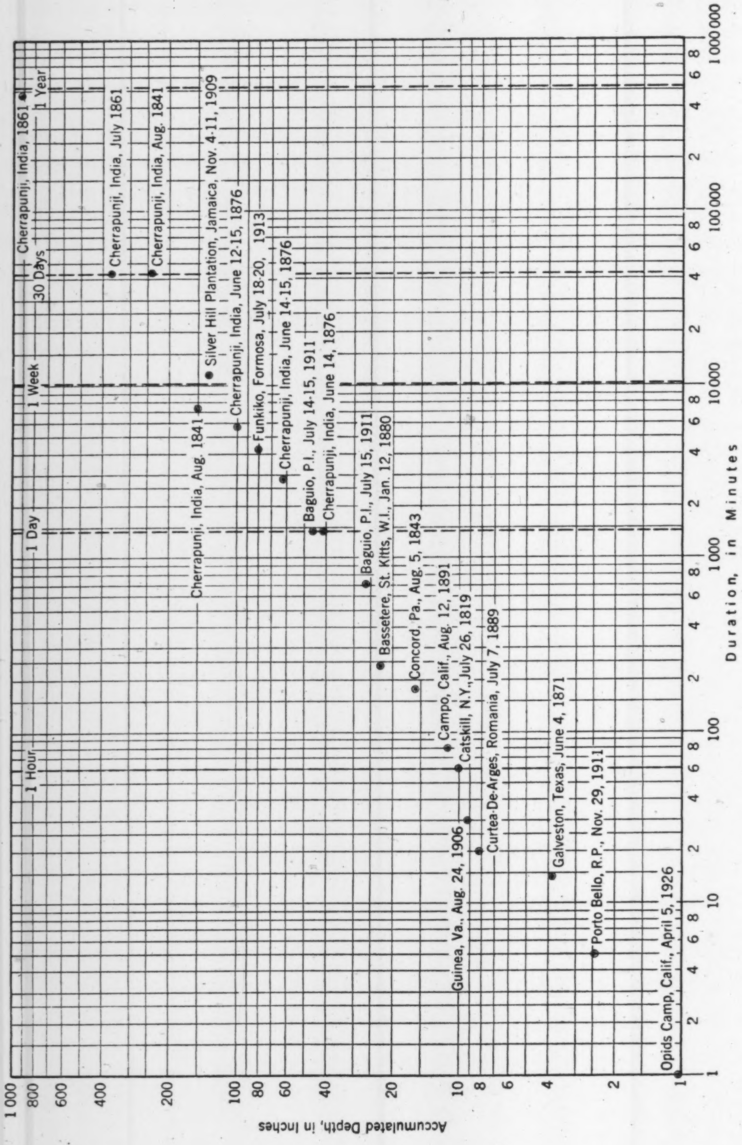

FIG. 7.—DURATION-DEPTH VALUES FOR POINT RAINFALL (WORLD'S RECORD)

THE MAXIMUM POSSIBLE OR ULTIMATE FLOOD

An immediate distinction to be made is that between the maximum possible flood and the maximum possible storm. Factors other than rainfall, such as melting snow, infiltration rates, and basin characteristics, enter into the determination of the maximum flood stage. The storm of September 11–13, 1878, produced more rain over smaller areas than did that of March 24–26, 1913. However, the former was the result of a decadent tropical hurricane which could not have occurred under conditions permitting a snow mantle over the upper Ohio Basin, whereas rainfall from a storm of the type and proportions of the latter could combine with snow melt under optimum cover and melting conditions to produce a flood of greater proportions. The maximum possible storm, then, is limited to that type which can produce the greatest amount of rainfall over a selected basin within a critical period fixed primarily by the concentration time for the basin and under conditions which are optimum for maximum snow melt and minimum infiltration and retardation.

Although rainfall amounts may be expected to increase as the record for a point or a small basin continues, it is a sound statistical inference that, within the average record period of about 50 years, every extensive region in the United States has experienced a storm which resulted from a critical combination of major factors and at least two of these have approached their physical upper limits. It is reasonable to assume also that at the end of an indeterminate period every basin in the region will have experienced the visitation of such a storm. The statistical evidence of these conclusions is supported by computations of maximum possible rainfall which are based on conservative theoretical assumptions.

Phenomenal precipitation records have been reported from various points over the world throughout the past 100 years. Their news interest has been greater than their value as records of flood-producing rains because no indication is given of the extent of the storm, of which they represent only a dimensionless point. Fig. 7 shows point rainfall depths accumulating throughout periods of varying durations. There is a well-defined upper limit. It should be noted that the lower range of the curve is well represented by values observed in the United States. Although a curve enveloping these points could be modified to represent average depth over specified area, its use in design would be extravagant in many cases, disregarding as it must the physiographic influences particular to the region in which the basin is located.

Limiting depth-duration curves for a number of basins in the United States are compared with that of world-wide point rainfall in Fig. 8. Differences in depth-range and curve-shape reflect differences in basin area and restraining regional influences which make it impossible for all basins throughout the country to have the same maximum rainfall experience. The primary objectives of the hydrometeorological studies have been to make it possible for the designer to consider economy by taking advantage of circumstances favoring a particular basin, while aiding him to gain security by disclosing the most critical storm-flood situation which his structure will ever be called upon to meet.

FIG. 8.—LIMITING DURATION-DEPTH CURVES

PRINCIPLES OF STORM TRANSPOSITION

Storm transposition is not a new idea. It is a comparatively simple procedure to place an isohyetal map in critical position over that of a basin and convert the rainfall into a flood wave at a selected point. In so doing the designer has merely stated, "Had this storm occurred over the basin under the assumed conditions of runoff, it would have produced a flood of these pro-

portions." He is not yet in position to know that the storm could have occurred within the season implied by the assumed conditions of runoff; nor that it could occur such a distance and direction from its actual location. Nor can he, if interested in maximum values, be sure that the storm could not have been much greater in magnitude.

To proceed beyond this point in reaching the objectives previously set forth, it is necessary to develop a philosophy which recognizes the limitations of basic data and scientific knowledge, strikes an intelligent balance between the empirical and the rational, resorts to theory as a guide in expressing qualified judgment, and in a common-sense fashion proposes to make the best use of whatever data are available—about 50 years of fairly dependable precipitation records, 40 years of acceptable synoptic weather maps, and a scanty 8 years of reasonably adequate upper-air data.

It is more the exception than the rule to find adequate record of hydrologic data on a basin designated for flood study. More often, it is necessary to anticipate the basin's future rainfall experience from an extensive study of the region in which the basin is located. It is known, to begin with, that the basin will ultimately (at the end of *X* years) produce a record of storm precipitation which will have in it one storm experience at or near the upper limit fixed by the characteristics of the region of which the basin is a part. If the basin approaches the region in size it will have this experience in a much shorter period than if it is small and storms entering the region have opportunity to center elsewhere.

As basins depending upon reservoir storage for flood control are usually much smaller than the region in which they are located, the procedure is usually to transpose to them those storms of record which, for a particular duration, have produced rainfall under conditions which are known to be supercritical. It would be possible, of course, to superpose all storms over the basin, plot average depth for the basin area for selected durations and obtain an enveloping curve, the increments of the curve becoming the synthetic design storm of typical pattern. The results of flood-storm analysis are given greater utility if area-duration-depth curves are prepared for the region which, under the assumptions of meteorological homogeneity, can be applied to any basin within it. In some instances it is necessary to transpose from one extreme to the other within a region, or between adjacent regions, in which case the transposed storm is adjusted to its physical upper limit for both the observed and transposed locations.

In Figs. 9 to 16 the assigned basin is shown in its relation to those storms contributing to or supporting maximum depth-duration values for the region. The depths indicated for each area are the average of actual rainfalls within a selected isohyet of major storms.

THEORETICAL DETERMINATION OF STORM RAINFALL

To determine theoretically the maximum possible precipitation over an area, it is necessary to develop an equation of flow. This equation expresses the obvious principle that the amount of precipitation is the difference between moisture inflow and moisture outflow.

FIG. 16.—WHITE RIVER BASIN UPSTREAM FROM MUD MOUNTAIN DAM SITE, WASHINGTON
It was Necessary to Analyze Twenty-Six Storms in Order to Identify the Two Representing Maximum Storm Conditions for This Basin

It is evident that moisture inflow will be proportional to the horizontal component wind velocity. The wind velocity in the free air, of course, is a function of the density and the pressure gradient. From a study of thousands of upper-air soundings, it has been found that, at moderately high levels, there exists on the average a direct linear relationship between temperature and pressure. For example, at 5 km, at a pressure of 560 millibars the temperature is found to be 0° C, and at 495 millibars the temperature is − 50° C. This relationship, by the equation

$$\frac{p}{T} = R\rho \quad \text{(1)}$$

also fixes the density, ρ. (In Eq. 1: p = atmospheric pressure, in millibars; T = temperature, in degrees absolute; and R = the gas constant for dry air.) In the foregoing example, the density for 0° C and 560 millibars is 713 g per cu m; whereas that for − 50° C or 495 millibars is 773 g per cu m. Thus the extreme wind will depend, in general, on the extreme temperature gradients aloft. Without delving too deeply into the subject, it may be stated that with the present-day knowledge of the thermodynamics of the atmosphere the limits of extreme temperature aloft can be determined with reasonable accuracy. These limits are found to agree reasonably with observed data. There are also a vast number of pilot-balloon and anemometer observations that have been used in determining the maximum values.

To produce heavy rain two conditions involving moisture must be fulfilled: The air must be saturated; and the temperature-lapse rate must be such that rising air would be in unstable equilibrium.

These requirements definitely establish the upper limit of moisture content of a column of air as a function of the dew-point temperature at a fixed level. The moisture content of an atmospheric column, expressed in terms of water, is called precipitable water (W_P), which is the total amount of vapor in the column, and not the amount that can be removed. The problem now is to determine that which can be removed.

Nature has various ways of producing rainfall, the convective process being considered the most efficient. From a detailed study of the seasonal variation of all the phenomena associated with convective overturning, the functional relationships shown in Fig. 17 between the size of the convective cell and moisture charge have been derived. Surface dew point can then be taken as the measure of the amount of precipitable water in the atmosphere under the two conditions previously stated. The W_P-curve shows that with a dew point of 55° F at the surface there is 1 in. of precipitable water in the air column above, whereas a surface dew point of about 71° F accounts for 2 in. of water in the column.

The idealized model of a convective cell shows the existence of three layers—the inflow layer, the layer of maximum lift, and the outflow layer. The model to the left has a height of 18,000 ft conforming to a surface dew point of 50° F, whereas that to the right shows the cell size fixed by a dew point of 80° F. Intermediate values are represented by the curves.

Knowing the total precipitable water in the column and the total lift experienced, the amount removed as precipitation, and called effective precipitable water (W_E), can be computed. These values are shown by the curve in Fig. 17. For example, in the case of a dew point of 55° F the total water in the column is 1 in., but only 0.55 in. can be removed.

The flow equation, then, is:

$$R = \int K\, v\, W_E\, dt \tag{2}$$

in which: K = a coefficient depending upon the basin characteristics; v = wind velocity in miles per hour; W_E = effective precipitable water in inches; and t = time in hours.

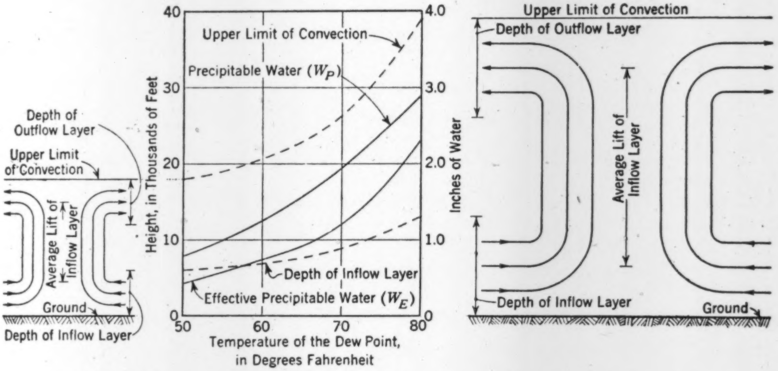

FIG. 17.—EFFECT OF MOISTURE CHARGE ON THE STRUCTURE OF A CONVECTIVE CELL

This means that the maximum precipitation will equal the product of the number of air columns moving into the basin and the maximum amount of moisture that can be squeezed out of each column by the most efficient natural process.

The minimum basin length for which the assumption of linear inflow is justifiable can be estimated from a comparison of the relative magnitudes of the vertical and horizontal components of the wind. If the width is approximately equal to the length, the minimum area is then about 1,000 sq miles for short durations, and about 10,000 sq miles for longer durations. A further restriction on potential rainfall is imposed by the maximum width of moist tongues which limits the moisture inflow column to a maximum of approximately 250 miles.

CONTRIBUTION OF SNOW MELT TO STORM RUNOFF

Precipitation in the form of snow acquires significance as a flood hazard when it accumulates over a basin beyond normal depth and water content. As a source of flood flow, snow can be considered a hydrologic element, but in

FIG. 18.—SNOW-HEAT-RUNOFF BALANCE; FUNCTIONAL RELATIONS AND INSTRUMENTATION

so far as the melting process is wholly involved with the factors, heat, moisture, and air movement, the problem more normally falls in the field of meteorology. The interrelationships between the atmosphere, the snow mantle, and runoff are shown in Fig. 18.

Engineers have made practical use of the fact that the temperature of the air is the most significant single factor in the melting process expressing this index in terms of degree-days above freezing. However, other sources of heat must be considered in any rational approach to snow-melt determination. These are—conduction from underlying soil, warm rain, radiation, condensation, and latent heat. Heat is transferred from the air to the snow surface through convection or turbulent exchange, a complex phenomenon which still defies exact analysis.

It is necessary, if the most critical snow-melt and runoff conditions are to exist:

1. That the snow is in a ripened state (that is, previous heat transfer has raised the temperature of the entire snow mass to the melting point; any further heating, therefore, produces melting);
2. That sufficient depth of frost exists in the underlying soil to check infiltration during the melting period; and
3. That rain occurs simultaneously with melting.

Under conditions (1) and (2) no temperature discontinuity exists at the soil-snow interface. This eliminates soil conduction as a factor in either melting or absorbing heat from the snow.

In ordinary circumstances, there is an appreciable heat exchange due to radiation. Snow absorbs a varying amount of solar energy or insolation depending on the character of its surface and angle of the sun. At the same time it radiates back to space as a "black body." Both the incoming and outgoing radiation are affected by the cloud cover which acts as a blanket to suppress radiational loss or gain. Continuous rain predicates an overcast sky and hence reduces the possible radiative heat transfer to a negligible amount.

Warm moist air transfers heat to the snow in two ways: By sensible heat exchange due to the temperature difference between the air and snow, and by the release of heat through condensation on the snow surface. This transfer of heat results in melting, or the conversion of the solid portion of the snow into liquid form at the rate of 1 g per 80 calories, the latent heat of fusion of ice. Since the heat of fusion of ice is only 80 calories and the heat of vaporization of water is 600 calories per g, the moisture condensed on the snow surface melts 7½ times its own weight of snow.

In moving air the vertical flow of heat and moisture depends on the degree of turbulence of the air. According to the theory of atmospheric turbulence, the temperature, humidity, and strong wind movement measured near the ground are approximately logarithmic functions of height. Within the higher wind-velocity range, therefore, melting rates can be reasonably defined in terms of velocity, dry-bulb temperature, and dew point.

For maximum melting rates accompanying rainfall, the air is close to saturation and, accordingly, the dew point approaches the dry-bulb temperature. Hence, the wind velocity and either dew-point or dry-bulb temperature characterize the air layer next to the snow and can be used in the determination of melting rates throughout the course of a critical storm. As an example, a limiting value of 55° F has been found to be representative of air temperature over snow cover for the upper Ohio Basin, while the warm sector of the storm remains over the basin. This value is to be reduced as the larger basins are considered, due to the influence of the extensive snow cover on the temperature of the lower layer of the atmosphere.

It has been generally conceded, heretofore, that flood threat from snow melt is proportional to the average depth of snow or its water equivalent over a basin. However, it is believed that a more accurate criterion for maximum contribution from snow melt is the existence of only a sufficient amount of snow in storage to react to the melting influences throughout the entire passage of a storm over the basin—the storm to be characterized by extreme temperatures and humidities. The presence of more snow than can be melted under these critical conditions may serve as a deterrence to runoff in the early stages of the storm; or at least it may exercise a regulatory influence on runoff. As melting continues, successive areas of the basin become depleted of snow, causing a progressive decrease in the contribution of melt to runoff. The sequence of melting takes a characteristic pattern beginning with a relatively sharp rise as temperature increases from freezing to some maximum value which is followed by a gradual decrease as snow disappears over the basin. Thus it is evident that the storm and not the depth and distribution of snow determines the amount of snow-melt contribution to the maximum possible flood.

Procedure in Developing the Maximum Possible Storm for an Individual Basin

Four years of intensive study have disclosed no method for determining maximum possible storm rainfall which will apply consistently to all basins. The Hydrometeorological Section of the Weather Bureau, in complying with its assignments, has had to begin with the unproductive end of the problem; that is, it has had to deal progressively with (1) an area sufficiently great to insure the inclusion of the region of meteorological homogeneity embracing the basin; (2) the major drainage area containing the assigned watershed in which orographic influences are to be evaluated; and (3) the assigned tributary basins themselves, where the problem reaches its most difficult phase in that both area and time are reduced to units smaller than those inherent in the available storm and rainfall data.

To present the quantitative results of storm transposition in suitable form for predicting the maximum possible flood, use is made of a procedure, familiar in engineering practice, involving the use of a duration-depth curve. Values of maximum rainfall for arbitrary periods of the storm sequence are plotted against corresponding values of duration which then define an enveloping duration-depth curve of the particular storm. Successive increments of rainfall for convenient units of time may be read off this curve and then rearranged, subject to possible meteorological restrictions, according to a pattern that would produce the maximum flood peak for a basin. This particular time distribution of rainfall is referred to as the critical arrangement of a storm.

The prevailing techniques are best illustrated from a recent study and report on the maximum possible precipitation over the Ohio River tributary basins above Pittsburgh, Pa. In this case, the storm of March 22–27, 1913, became the key storm which, after modification and adjustment made necessary by transposition, contributed the controlling points of the limiting depth-area-duration curves. The storm of March 16–19, 1936, which caused the greatest flood of record at Pittsburgh, and the storm of January 20–25, 1937, similar in type to that of March 19, 1913, were analyzed in their actual and transposed positions.

A typical storm analysis leading to the determination of the maximum possible precipitation over a particular river basin is presented in that of March, 1913. This storm began with the rapid northeastward movement of a low pressure area and a relatively slow eastward movement of the cold front which finally became stationary over the northern tributaries of the Ohio River.

No upper air data are available for March, 1913, but by comparison with storms of recent years it can be inferred reasonably that there must have been an intense cyclonic circulation of cold air aloft over the Central Plains and upper Mississippi Valley region, and a strong west-southwest to east-northeast flow of moist tropical air over the Ohio Valley. The sharp contrast of heat properties between these two air masses made available large quantities of potential energy which could be utilized in releasing excessive amounts of precipitation over a narrow band. The boundary between the two air masses was obviously unstable, thus tending to be broken intermittently by intense wave developments of small magnitude. These caused sharply alternating fluctuations of cold dry air and warm moist air to move along the frontal zone. The large-scale, up-glide motion of the warm air over the cold air tended to prolong the rainfall, but it was the sudden lifting and intensely localized convergence associated with the minor waves which caused intermittent occurrences of intense rainfall.

Such minor waves appear to move in a general eastward direction, but it is almost impossible to predict at what point they will reach the maximum of their intensity. Also, in the extreme case a number of these waves may successively concentrate their activity at approximately the same point, thus accumulating a small but intense center of rainfall. Fortunately, this concentration of rainfall on small areas usually occurs at the expense of rainfall over the surrounding areas, and for basins as large as 20,000 sq miles it is reasonable to assume that in a period of 24 hr or less the concentration observed in March, 1913, was near the maximum.

In considering the transposition of the March, 1913, storm to the Ohio tributaries above Pittsburgh, there were two questions to be answered: (1) Could the storm have been greater in its original position? (2) How much increase or decrease should be allowed in transposing it?

The following steps were taken to answer these questions:

(1) Analysis of the weather charts on the dates of heaviest rainfall showed that a dew point of 64° F was representative of the moisture charge of the warm sector in the storm area. This corresponds to $W_e = 0.88$ in.

(2) The analysis of maximum possible dew points from the Gulf of Mexico to Pittsburgh for various seasons revealed that in late March in the vicinity of the 1913 storm, a dew point of 69° F ($W_e = 1.13$) was possible. In other words, the March, 1913, storm rainfall could have been 28% greater or 128% of the observed average depths.

Maximum possible dew points at Pittsburgh indicate a dew point of 63° F ($W_e = 0.84$) for late March. Therefore, the maximum possible storm of type I near Cincinnati, Ohio, would have to be reduced in the ratio of 1.13 to 0.84 in transposing it to the Pittsburgh area. This represents a 26% reduction in rainfall amounts.

It is realized that no statistical approach can provide a valid adjustment factor for type I storms occurring near Cincinnati and transposed to the Pittsburgh area. However, the comparative data in Table 2 are in general agreement with the fact that the maximum possible storm values will be greater near Cincinnati than near Pittsburgh.

TABLE 2.—COMPARISON OF AVERAGE RAINFALL (IN INCHES) AT CINCINNATI, OHIO, AND PITTSBURGH, PA.

No.	Description (1)	Cincinnati (2)	Pittsburgh (3)	Ratio, $\frac{\text{Col. (3)}}{\text{Col. (2)}}$ (4)
1	Annual precipitation	38.41	35.81	0.92
2	March precipitation	3.82	3.10	0.81
	Rainfall, Type I Storms:			
3	Greatest 35 storms	1.44	1.05	0.73
4	Greatest 10 Pittsburgh storms	2.73	2.14	0.78
5	Greatest 35, 12-hr storms	0.42	0.31	0.74

The value of 26%, computed by the dew-point technique, was accepted and used in the following adjustment: Considering the observed depths in the March, 1913, storm equal to 100%, the maximum possible type I storm in the same locality would be 28% greater or equal to 128%. However, this maximum possible storm must be decreased 26% when transposing it over the Ohio River above Pittsburgh. The maximum possible transposed storm therefore becomes 95% of the observed.

The same result can be reached quite simply by adjusting the observed 1913 depths to the maximum possible dew point at Pittsburgh. The effective precipitable water for the respective areas was 0.88 in. in the actual storm and 0.84 in. (the maximum possible) at Pittsburgh. This is a 5% decrease. Therefore, in transposing the 1913 storm to the Ohio tributaries above Pittsburgh a decrease of 5% was applied to all depths for all durations, on the assumption that the storm could have been greater in its original locality, but could not have been so great if the storm had centered over the Ohio tributaries above Pittsburgh.

In regard to the orientation of isohyetal patterns resulting from type I storms, it must be emphasized that such storms occur with upper-air currents from the west-southwest or southwest, and rainfall must necessarily take place along a band which is at right angles to the major axis of the Pittsburgh basin. Since this particular direction of flow is necessary to bring moisture, unaffected by topography, into the basin, there can be no justification for changing the orientation of the original storm pattern. For the foregoing reasons a mechanical transposition without re-orientation was considered most representative of the March, 1913, storm over the Ohio tributaries above Pittsburgh.

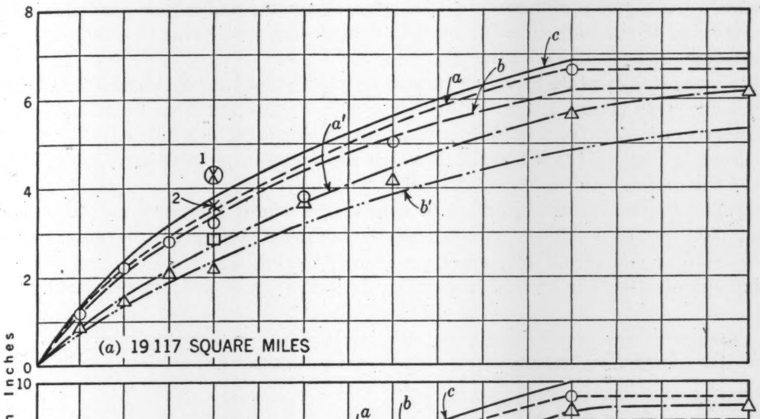

FIG. 19.—DURATION-DEPTH CURVES OF MAXIMUM POSSIBLE RAINFALL; STORM TYPES I AND II

Two typical groups of duration-depth curves are shown in Fig. 19. Each block in the diagram contains a family of five curves applicable to the area of a particular subdivision of the basin. Two curves, one for each of the major storms classified as types I and II, represent duration curves of rainfall as it actually occurred over the upper Ohio Basin (curves a and b, Fig. 19). Two other curves give corresponding values of rainfall obtained by transposing these storms to the most critical position over the basin (curves a′ and b′, Fig. 19). The enveloping curve is the duration-depth curve of maximum possible rainfall, representing as it does an upper limit fixed by actual values which have been increased with meteorological justification and modified according to the influences involved in transposing the storms to their assumed locations (curves c, Fig. 19).

Two additional 24-hr values have been plotted for the total basin (19,117 sq miles). One (Point 1, Fig. 19(*a*)) is the value computed from theoretical considerations involving moisture charge and velocity of air inflow. The other (Point 2, Fig. 19(*a*)) is the value which recognizes a possible error of 20% in the theoretical computation.

The maximum contribution to runoff from snow melt will result from a combination of maximum melting rates, maximum storage of free water in the snow and a uniformly deep snow cover over the basin. A series of snow-melt increments (see Fig. 20(*a*)) have been derived from principles previously described, assuming the distribution of snow cover which will respond most actively to the series of meteorological events characterizing the maximum possible storm.

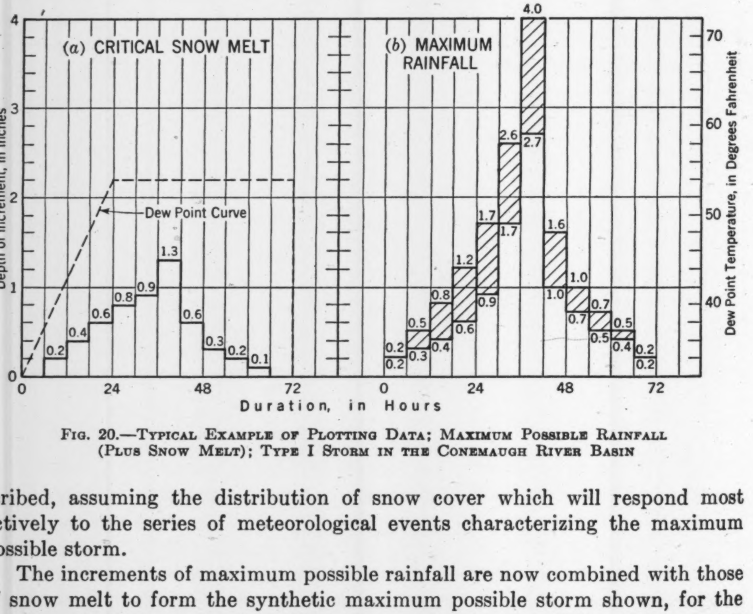

FIG. 20.—TYPICAL EXAMPLE OF PLOTTING DATA; MAXIMUM POSSIBLE RAINFALL (PLUS SNOW MELT); TYPE I STORM IN THE CONEMAUGH RIVER BASIN

The increments of maximum possible rainfall are now combined with those of snow melt to form the synthetic maximum possible storm shown, for the Conemaugh River Basin (as a typical example), in Fig. 20(*b*). The rainfall blocks have been arranged in an order which associates the highest rate of snow melting with the highest rate of rainfall, both being compatible with the meteorological features of storms of this type. Since the first 24 hr of the storm sequence is fixed by the meteorological situation and the accompanying snow melt, the rainfall-snow-melt increments of this period should not be interchanged among themselves or with those of the last 48 hr of the storm. Increments within the last 48 hr of the storm, however, may be interchanged as desired. The individual snow melt and rainfall increments must be considered inseparable, the necessity for which is readily seen from a consideration of the snow-melt computation procedure. These restrictions apply to all sizes of drainage basins.

The Bibliography in Appendix 1 will serve as a guide to selected reading for those whose interest in meteorology has carried them beyond the scope of this paper.

The writer should like to close by expressing his conviction that an engineer is not prepared to deal adequately with precipitation, the principal hydrologic factor, until he has gained a working knowledge of the processes which take from the sea, transport, and precipitate over the land the myriad of rain drops constituting a great storm. Thus equipped he will find his concepts broadened, his techniques made flexible, and his judgment strengthened.

ACKNOWLEDGMENTS

The hydrometeorological studies described herein are conducted for, and in cooperation with, the Engineer Department, Corps of Engineers, U. S. Army. The writer wishes to acknowledge with thanks the valuable assistance of Albert K. Showalter, Samuel B. Solot, Phillip Light, Alexander L. Shands, and other members of the Hydrometeorological Section, Weather Bureau.

APPENDIX 2

GLOSSARY OF METEOROLOGICAL TERMS

Synoptic Chart.—A chart, such as the ordinary weather map, which shows the distribution of meteorological conditions over an area at a given moment.

Anticyclone.—An area of high barometric pressure and its attendant system of winds (clockwise in the northern hemisphere).

Cyclone.—An area of low barometric pressure with its attendant system of winds (counterclockwise in the northern hemisphere).

Air Mass.—An extensive portion of the earth's atmosphere approximating horizontal homogeneity.

Front.—The boundary between two different air masses.

Polar Front.—The surface of discontinuity separating an air mass of polar origin from one of tropical origin.

Cold Front.—Front at which relatively cold air displaces warmer air.

Warm Front.—Front at which relatively warm air displaces colder air.

Quasi-Stationary Front.—Front whose movement is such that there is no appreciable displacement of warm air by cold air or vice versa.

Cyclogenesis.—Process which creates or develops a new cyclone, or which produces an intensification of an old one.

Frontogenesis.—Process which creates a front or intensifies an existing front.

Frontolysis.—Process which tends to weaken or destroy an existing front.

Occlusion.—Process whereby the air in the warm sector of a cyclone is forced from the surface to higher levels.

Occluded Front.—The type of front resulting when a cold front overtakes a warm front.

Cold Front Type Occlusion.—Occlusion in which cold air in rear of the cold front is colder than and underruns the cold air in advance of the warm front.

Warm Front Type Occlusion.—Occlusion where cold air in rear of cold front is warmer than cold air in advance of warm front.

Isentropic Chart.—Synoptic chart plotted on a surface of constant potential temperature, and is so called since a surface of constant potential temperature, if unsaturated, is also a surface of constant entropy.

Potential Temperature.—Temperature which an air parcel would have if expanded or compressed dry adiabatically to a standard pressure of 1,000 millibars.

Equivalent Potential Temperature.—The potential temperature of an air parcel after all the latent heat of condensation of the contained water vapor is realized.

Dew-Point Temperature.—The temperature at which, under ordinary conditions, without change of pressure, condensation begins in a cooling mass of air.

Wet-Bulb Temperature.—Lowest temperature to which air may be cooled by evaporating water into the air at the same barometric pressure.

Specific Humidity.—Ratio of the weight of water vapor to that of air in a given sample, in grams per kilogram.

Lapse Rate.—Rate of decrease of temperature in the atmosphere with height.

Dry Adiabatic Lapse Rate.—Rate at which an ascending body of unsaturated air will cool due to adiabatic expansion, equal to approximately 1° C per 100 m.

Pseudo-Adiabatic Lapse Rate.—Lapse rate equal to the rate at which an ascending body of saturated air will cool during adiabatic expansion. Its value is not the same under all conditions, but is never greater than the dry adiabatic rate.

Precipitable Water.—Total water vapor contained in an atmospheric column of unit cross-section area expressed in terms of a column of water of the same cross-section area.

Effective Precipitable Water.—The greatest amount of precipitable water which can be removed from an atmospheric column by convective action.

Tongue.—A projecting stream of air which may be dry or moist, revealed by the isentropic chart or atmospheric cross-section charts.

Trough.—An elongated area of low barometric pressure.

Stability.—Thermodynamic state in which vertical displacements are resisted.

Instability.—Thermodynamic state in which vertical displacements are favored.

Convective Process.—Process, mechanical or thermal, causing the upward or downward movement of a limited portion of the atmosphere. Cumulus type clouds are indicative of the occurrence of convective processes.

Level of Free Convection.—Level in the atmosphere at which, when reached, an air parcel is warmer than its surroundings and will continue to be displaced upward.

Lifting Condensation Level.—Level in the atmosphere at which, when reached, an air parcel will cool at the pseudo-adiabatic rate.

Conditional Instability.—Thermodynamic state which is unstable for saturated, but stable for dry or unsaturated, air.

Convective Instability.—Thermodynamic state of a layer which will become unstable after sufficient lift.

Up-Slope Winds or Up-Glide Winds.—Winds occurring when there is a net flow of air moving up a slope. When the slope is a front, the warm air moves up with respect to the colder air beneath the front.

Down-Slope or Down-Glide Winds.—Winds occurring when there is a net flow of air moving down a slope.

Orographic Rainfall.—Rainfall caused by the interference of rising land in the path of moisture-laden wind. A horizontal air current striking a mountain slope is deflected upward and the consequent dynamical cooling associated with the expansion of the air produces rain if the air contains sufficient aqueous vapor.

Convergence.—Condition that exists when distribution of winds within a given area is such that there is a net horizontal inflow of air into the area.

Gradient Wind.—The wind resulting from the balance (neglecting friction) between the force due to the pressure gradient, the apparent deflecting force of the earth's rotation, and the centrifugal force due to the curvature of path.

Geostrophic Wind.—The wind resulting from the balance of the force due to the pressure gradient and the apparent deflecting force of the earth's rotation, neglecting curvature of path and friction.

DISCUSSION

Edgar Dow Gilman,[3] M. Am. Soc. C. E.—Much valuable data are contained in this paper, including theories and conclusions on storms and precipitation. Precipitation is undoubtedly one, but only one, of the major factors in the production of floods and is not in itself a controlling factor. Although the subject of precipitation is handled interestingly in this paper, the title, "Flood Estimating," appears to be broader than the material actually covered. For example, the heading of one section is "The Maximum Possible or Ultimate Flood," in which the author sets forth the maximum possible or ultimate precipitation, which does not seem to the writer to be synonymous with floods.

From a study of Ohio River flood records and flood observations in more recent years, there appear to be two factors in floods, regarding which more data and study would be enlightening. The first is the variation in the longitudinal profiles of flood flow and crests. The second is the effect on such profiles of the "timing" of the tributary crests at their outlets relative to the moving crest in the river.

Different floods have quite different longitudinal profiles. When these profiles are plotted as of any instant, at wherever the crest is at that instant, with miles as the horizontal axis and feet elevation as the vertical axis, it is found that the slopes in front of, and behind, crests are quite dissimilar in different floods—some will be gradual and some will be sharp. The lengths of the higher elevations or crests will also vary; some will be short and some will be long. How high a flood is produced in a big river with many tributaries, when there has been a given precipitation over the watershed, depends upon how that volume of water is stored in the moving flood. A given volume in a long, flat crest with gradual slopes will not result in as high a flood as if the same volume were contained in a short, sharp crest with steep slopes. This introduces the factor of "timing"—that is, whether crests in tributaries reach their mouths at such a time as to add to the height or length of the crest in the river or some of each.

In 1913 the Miami River (which enters the Ohio River about 17 miles below Cincinnati) reached its crest on March 26, producing the great Dayton flood. On that date the Ohio River was 4 ft under the flood stage of 52.0 (gage height) at Cincinnati. This caused a pool in the river, and, for a considerable period, water was actually flowing upstream in the Ohio River. In the meantime, a crest in that river was on its way down, but did not reach Cincinnati until April 1, when it crested with a gage height of 69.9, the second greatest recorded flood stage at Cincinnati up to that time (exceeded in 1884 and 1937). The gage height of the Miami River at Hamilton, Ohio, was 34.0 ft at its crest on March 26; and, on April 1, when the Ohio River crested at the mouth of the Miami River, the gage height of the latter was only 4.0 ft. In these six days the Miami River had dropped 30 ft. Presumably the greater portion of the volume of flood discharge from the Miami River added to the length of the flood crest of the Ohio River, rather than to its height, which was probably increased somewhat because of the additional water ahead of the crest. However, the problem is what would have been the effect on this Ohio River crest if the greatest discharge of the Miami River had reached its outlet on March 31, April 1, or April 2, instead of on March 26?

---

[3] Director, Dept. of Public Utilities, Cincinnati, Ohio.

Time obscures details and, in the minds of most people, the 1913 flood in the Miami River and the 1913 flood in the Ohio River at Cincinnati are considered one and the same flood; but the six-day interval between them, with due regard to the flashy character (rapid rise and fall) of floods in this smaller river, probably was a vitally important timing.

That all tributaries to a river would release their maximum discharge at the exact time to produce the greatest increase in height of the crest of the major river as it passed the mouth of each tributary might be equivalent to assuming an improbable, if not an impossible, series of cumulative coincidences. With the maximum precipitation over the watershed of each tributary and such an assumption, a theoretical maximum flood could be shown that at least would be interesting. Although such a drastic eventuality will never be realized, it seems true that floods in major rivers, such as the Ohio, vary in height as more or fewer of the total number of tributaries approach such timings in their discharge; and that, because of variations in the number of such coincidences, it is a practical possibility to have higher floods with other than the maximum precipitations. In other words, unless the precipitation is of very long duration over the entire watershed of a big river, it cannot be stated that the greatest precipitation will necessarily produce the greatest floods.

The writer would suggest again that all river gage heights be read in sea-level elevations. Past records from existing gages could be referenced to the new base and not be lost. Such procedure would add materially to the information to be gained from reading a table of gage heights throughout the length of the Ohio River. It seems unnecessarily confusing to the writer to refer to a gage height of 30 ft in the Miami River at a time when the gage height in the Ohio River is 48 ft, and, at the same time, to realize that water was flowing from the Miami River into the Ohio River.

CLARENCE S. JARVIS,[4] M. AM. SOC. C. E.—This timely, concise report on "relative successes and failures" has a special appeal because of its clarity of concept, its modesty of claims, and its wealth of significant data in their proper relationships. The final paragraph preceding "Acknowledgments" deserves particular emphasis, which may be afforded by an illustration from the writer's personal experience.

In connection with a paper on the characteristics of flood flow (23), the insertion of a few brief paragraphs on rainfall phenomena, particularly in their relation to floods, was found desirable; and several months of study under the local Weather Bureau officials were required before that portion of the text attained its final form. Incidentally, that course of intensive study opened the way to the writing of a companion paper (24), for which the nucleus was prepared and diverted from the earlier paper. Fully five years were needed to encompass the first phase of that project, namely, the assembly and summarization of representative precipitation data from stations throughout the world. Basic principles and interesting relationships were set forth as a preliminary to solving some of the outstanding problems involving rainfall and resulting runoff. The data proved to be so abundant and varied, and the field for investigation so broad, that it seemed best to publish the assembled records with such brief discussion of fundamentals as had been prepared and to invite cooperation from all hydrologists, engineers, and interested scientists or research workers in the interpretation of facts brought forth and in the extension of the hydrologic field.

---

[4] Hydr. Engr., With Office, Chf. of Engrs., Washington, D. C.

In the course of writing chapters for recent volumes, all dealing with some phase of hydrology, the writer has observed that the progress is so rapid that extensive study is required for one to avoid becoming out of date.

After reviewing the most notable recent advances in practical hydrology and meteorology now largely associated with the demands, as well as the facilities, afforded by aeronautics for obtaining three-dimensional weather data, one is impressed with the insignificance of any new ideas he has brought forth, in comparison with the important problems awaiting and inviting solution. Frankly, within the writer's experience, some of the methodology and findings that rated highest according to his judgment were promptly relegated to the rôles of "incomplete forward passes." Probably the surest way to have new procedures adopted for general use is to have them devised and announced by responsible, thoroughly organized agencies. This leads inevitably to the conclusion that such official representatives should continue to set the pace and to direct the vanguard in notable advances. Unofficial utterances possibly may attain the importance of "aerial reconnaissance," or even desultory "bombing" of a hostile, unknown area. Complete mastery of the situation will continue to depend on the organized efforts of "ground troops" and their occupation in force.

Although accepting the authoritative data and their analysis as presented in this paper, the writer submits herewith some qualifying notes and queries, which seem to invite further study:

1. Solar radiation may contribute directly to the heating of the atmosphere through which it passes—probably somewhat less than 10% for clear, dry air when the sun is near the zenith, but correspondingly more as the rays become more inclined. Examples of equivalent transparent masses are 34 ft of clear, placid water or 14 ft of the best grade of glass. With the formation or the gathering of cloud masses, the reflecting and radiation surface is elevated high above the ground and applied to the heating of a lesser mass of atmosphere, in a rarefied condition, resulting in pronounced thermal changes and gravitational instability therein.

Is it not quite probable that much of the turbulence and convective movement results directly from the local effects of solar energy applied to the upper surface of the cloud masses? Such heating should dispel the upper fringe of cloud forms, and the induced buoyancy would give an upward component to the air column's movement.

2. The author and other writers assume that contained in the atmospheric column covering the globe is a single inch of water, on an average, with appropriate excess in torrid regions and deficiency near the poles. If this is correct, it seems inconsistent to assume a depth of only 0.88 in. for the precipitable moisture on the date of heaviest rainfall, during the storm which most nearly represents the maximum possible. It is of record that more than 1 in. fell at Cincinnati, Ohio, in the hour extending somewhat beyond midnight of March 25–26, 1913; and considerable areas recorded as high as 6 in. in 24 hr. It would have required more horizontal wind movement than has been recorded to account for the seven complete displacements and renewals of air columns over those extensive areas of high rainfall; and those same areas would have been flanked by regions of deficient rainfall, if the air masses had been "wrung dry" in the convective cells.

On the contrary, the 1,100 sq miles of area with precipitation depth 6 in. or greater were flanked by areas of moderate rainfall depth; 12,000 sq miles with 4 in. or more, and some 20,000 sq miles with 3 in. or more, and much greater areas for the 2-in. and 1-in. isohyetals. Assuming that the width of incoming tropical airstream was 200 miles, then the movement required for extracting the average depth of 4.7 in. within the 4-in. isohyetal is expressed by:

TABLE 3.—STORM OF MARCH 24 TO 27, 1913, AS RECORDED AT U. S. WEATHER BUREAU STATIONS IN CINCINNATI (C) AND DAYTON (D), OHIO

March	TEMPERATURE, IN DEGREES FAHRENHEIT						WIND VELOCITY, IN MILES PER HOUR				PRECIPITATION (INCHES OF DEPTH)	
	Maximum		Mean		Minimum		Maximum		Mean			
	C	*D*	*C*	*D*	*C*	*D*	*C*	*D*	*C*	*D*	*C*	*D*
24	70	64	62	58	55	51	18 W	50 S	....	18	2.21	2.95
25	70	59	63	54	56	48	26 SW	46 S	....	....	4.15	2.27
26	57	56	47	44	37	32	17 NW	....	....	....	1.11	....
27	37	32	32	28	27	23	22 W	....	....	....	trace	1.90 (estimated)

Horizontal wind velocity in miles per hour, $V = \dfrac{4.7 \times 60}{0.88 \times 24} = 13.3.$

To supply the larger areas with lesser depths included in this particular storm pattern, much greater wind velocities would have been required. Assumption of greater precipitable depths of moisture would reduce the corresponding wind movement, at least to stay within the maximum velocities observed at the Cincinnati station, as recorded in Table 3.

Quoting from a previous paper (24*a*):

> "The condensation of 1 in. of rain releases the equivalent of 2 h.p.-hours of energy per sq.ft. of surface, or nearly 87 000 h.p.-hours per acre. If applied exclusively toward heating the first mile in height of air column above sea level, the resultant increase of temperature would be 30° Fahr., or more, depending on the density and humidity; and this thermal change would cause an expansion ranging from 6 to more than 10 per cent. The resulting buoyancy would be of the same order as that possessed by ice or logs floating in water."

There is no more assurance of confining the released energy to the heating of the lower mile of the atmospheric column than of applying similar heat units solely to the melting of snow cover as the vapor condenses upon its surface. A considerable time factor is required to complete the transfer of the heat units—some portion to the condensed moisture, some to the snow, and the remainder to the surrounding atmosphere. Furthermore, the natural surface runoff on perceptible slopes may limit the time of contact for the condensed moisture and the snow surface, thus preventing complete transfer of the released energy. During a cold spell following a heavy snowstorm in Washington, D. C., attempts were made to remove some of the cluttering snow heaps at intersections by the application of blowtorch flames to tunnel through the compact mass. The slight trickles of water reaching the gutters and the slow progress in snow removal plainly demonstrated that heat was being dissipated into the surrounding atmosphere instead of into the packed snow.

Inasmuch as the first volume of daily *Climatological Data* began in January, 1914, before much progress had been made in regular observations aloft, it may be well to present some of the available records, pertaining to the storm of March 24 to 27, 1913, in Ohio (see Table 3).

In the absence of direct observations as to upper air conditions, only estimates and assumptions are available. Nevertheless, condensation and precipitation were proceeding vigorously at the prevailing temperatures as observed at U. S. Weather Bureau stations; therefore, the actual dew point for some of the air masses involved in the turbulence might have been somewhat higher than the station temperatures. At Kew, near London, England, it was observed that the normal variation of dew point under foggy conditions was nearly half the diurnal variation in station temperature, thus amounting to some 13° C or 23.4° F (17*a*). W. Napier Shaw has presented tabular data (25) showing the water-vapor capacity of saturated air up to 30,000 ft above sea level as more than 0.73 in. in depth when the temperature at the base of the column is 50° F. Field observations at St. Louis, Mo., with a maximum observed temperature of 77° F, gave the atmospheric moisture capacity at saturation as 2.28 in., of which 1.67 in. was subject to precipitation; and other stations recorded moisture capacities of 2.60 and 2.92 in., respectively, for temperatures of 77° and 73°, with 1.67 and 1.41 in. subject to precipitation (26).

3. Whether the temperature gradient was subjected to inversions, increasing the moisture capacity, or to other irregularities resulting from the general turbulence, the heavy precipitation and the corresponding release of energy from the condensing vapor was not recorded, as upper air data were not observed. No one can say authoritatively and convincingly, therefore, that the total moisture content of the air column was only 1.40 in. nor that the precipitable moisture at the beginning of the storm was only 0.88 in. or double that amount. Of vastly more importance are the foresight, determination, and courage displayed both in the establishment and the maintenance of the Hydrometeorological Division and in its guidance toward the solution of vital problems affecting the national security and economy.

After all, the rainfall-runoff relationship is a simple one, despite the complicated, elusive, and partly indeterminate factors involved. One of the important keys to its solution, the "unit hydrograph" (27), written following the

November, 1927, floods in New England, seems destined to stand as a monument to organized research. This clear concept, by L. K. Sherman, M. Am. Soc. C. E., was developed further by Mr. Bernard's keen perception and adroit adaptations—together with the determined efforts of the U. S. Geological Survey; the State of Pennsylvania; the Corps of Engineers, U. S. Army; the U. S. Weather Bureau; the Soil Conservation Service; and other federal or local agencies—to provide a safe and logical basis for analysis, forecasts, and design related to floods and plans for their control. Naturally, important contributions have come from the vanguard among consultants, such as W. W. Horner, M. Am. Soc. C. E., Robert E. Horton, M. Am. Soc. C. E., and Horace W. Wood, Jr., M. Am. Soc. C. E. Mr. Wood's work, "Flood Flow on Missouri Streams" (28), gives an unusually clear résumé of methods now in vogue, including empirical and other formulas together with the "unit hydrograph" in their appropriate settings.

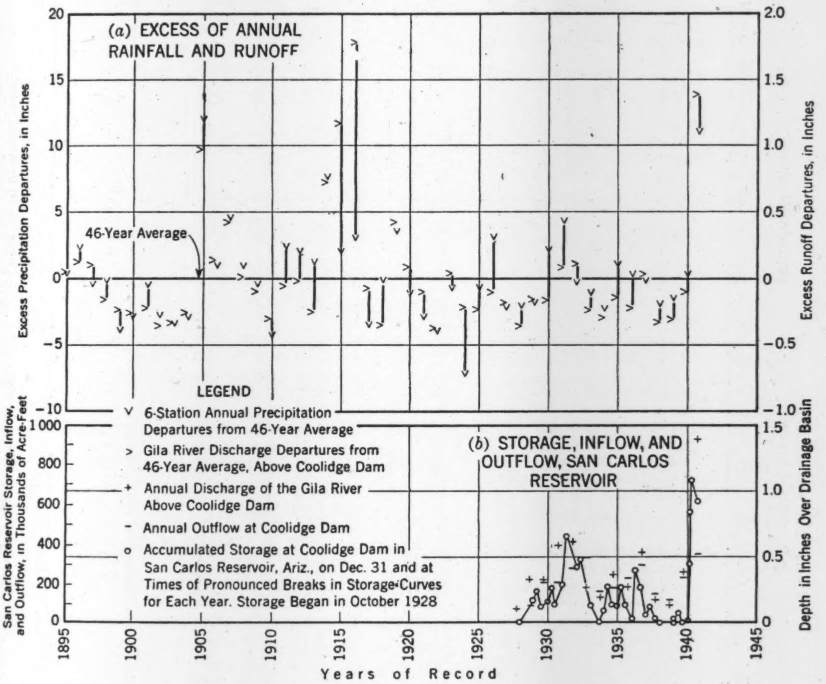

FIG. 21.—GILA RIVER BASIN, AS OBSERVED AT COOLIDGE DAM, ARIZONA; ANNUAL PRECIPITATION AND RUNOFF EXCESS COMPARED WITH 46-YR AVERAGES

In spite of the varied topography and hydrologic as well as meteorological characteristics of the semiarid Southwest, the writer has found some very consistent relationships between rainfall and runoff excess or deficiency, year by year, from 1895 to 1941, inclusive.

The 46-yr average values are as follows:

Description	Gila River basin	Rio Grande basin
Precipitation, in inches	11.80	12.83
Runoff:		
Inches of depth	0.492	0.840
Cubic feet per second	968	1,500
Thousands of acre-feet per year	339	1,084
Area:		
Square miles	12,880	24,200
Thousand acres	8,243	15,488

The foregoing yearly means of rainfall depths at six stations on the Gila River watershed above Coolidge Dam, Arizona (Fig. 21), and of the nine stations on the Rio Grande watershed above Elephant Butte, N. Mex. (Fig. 22), were subtracted from the respective 46-yr means for those same station groups, to give the excess or deficiency for each year. Corresponding departures from annual mean runoff depths per year throughout the same record periods, plotted on a scale 10 times as great, show fair agreement generally,

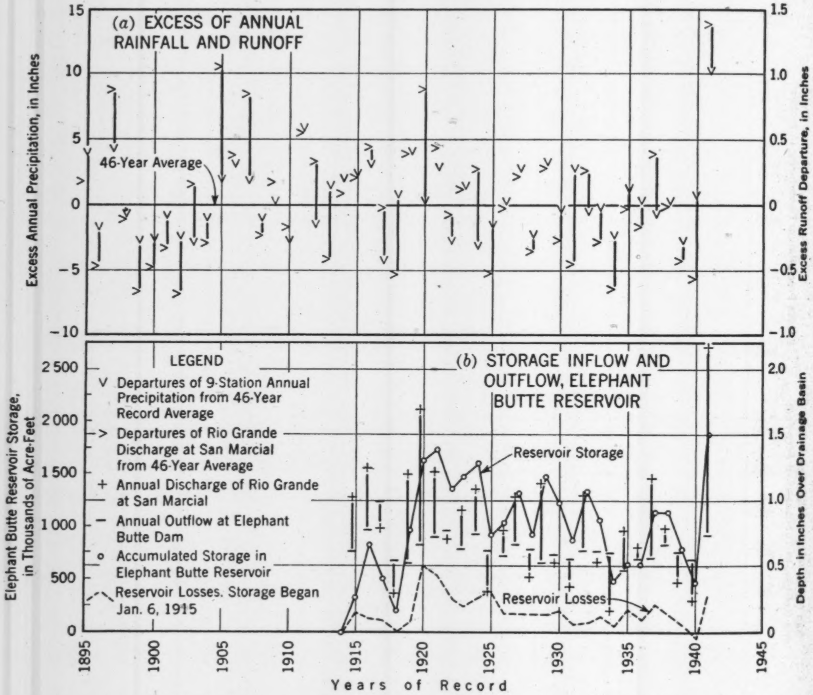

FIG. 22.—RIO GRANDE BASIN, AS OBSERVED AT SAN MARCIAL DAM, NEW MEXICO; ANNUAL PRECIPITATION AND RUNOFF EXCESS COMPARED WITH 46-YR AVERAGES

with several of the years recording nearly coincident plottings. Likewise, the cumulative effect of a series of relatively wet years, such as 1918 to 1920 on the Rio Grande and 1905 to 1907 or 1911 to 1916 on the Gila River, and the subnormal rainfall generally from 1932 to 1940 on both watersheds, culminated in great departures from normal runoff and associated storage volumes, either in underground or in major surface reservoirs.

In 1941, with rainfall nearly double the normal, runoff was recorded representing nearly 4 times the mean for the Gila River, and more nearly 2.7 times the mean for the Rio Grande at Elephant Butte (where the excess was 1.7 times the mean).

Sufficient data were available to determine the annual losses in Elephant Butte reservoir, with a mean of about 200,000 acre-ft and a maximum of 648,000 acre-ft in 1920 (during the initial filling of the higher contours which required heavy contributions to bank storage). During 1918, the reservoir losses were nearly balanced by return flow from bank storage; and, during the critically dry season of 1940, the return flow not only equaled the storage losses, but also provided a dividend of 48,000 acre-ft for use in the lower valley.

A similar approach would disclose interrelationships between either monthly or daily rainfall and runoff, provided all of the principal factors, such as antecedent rainfall and temperature, and their effect upon soil moisture, are given due consideration. Similar relationships for the time, distance, and volumetric quantities, which affect both peak and total discharge at successive stations along the river channel, would be found.

Neither the microscopic approach, through rainfall intensities per hour or minor fraction thereof, nor the telescopic approach, through record means and departures therefrom is capable of answering all the vital questions pertaining to water supply, flood forecasting, and best schedule for release of reservoir storage. Both of those approaches, and others occupying intermediate ground, should be regarded as independent witnesses contributing evidence on the problems involved. The author has done much toward integrating the available records as well as the logically derived implications, and thus has completed one of the "forward passes" previously attempted by the writer (23)(24) before such a wealth of data, methodology, and coordinated teamwork was at hand.

IVAN E. HOUK,[5] M. AM. SOC. C. E.—Estimates of maximum possible flood flows must often be made for use in designing spillways and other hydraulic structures, as well as for use in planning major flood control projects. The author's comprehensive discussion of meteorological problems involved in such estimates shows that real progress is now being made on this important phase of hydrologic work. The accompanying data regarding maximum possible storms and their relation to maximum possible floods should prove valuable to practicing hydraulic engineers, to flood control specialists, and to all scientists actively engaged in meteorological and hydrological researches.

Naturally, the occurrence of the maximum possible storm on a given drainage area does not necessarily mean the occurrence of the maximum possible flood, even though the duration of the storm rainfall may equal the time of concentration for the given area. This is especially true for relatively large drainage basins in temperate zones, where conditions of snow cover and surface soil moisture content constitute important influences on rates of flood runoff. It gradually becomes less certain as the size of the basin decreases. In the case of a comparatively small area subject to intense rainfall of the thunderstorm or cloudburst type, the maximum possible flood probably is caused by the maximum possible storm, since the rate of infiltration (even under optimum conditions) usually is only a small proportion of the rate of cloudburst precipitation.

---

[5] Senior Engr., Technical Investigations, Bureau of Reclamation, Denver, Colo.

The world's records of most intense point rainfall shown in Fig. 7 suggest the question as to whether or not they represent maximum possible rates of rainfall. The question is primarily of academic interest, since it probably never would be economically advisable to design bridges, culverts, sewers, spillways, or other hydraulic structures for the intense rates of runoff which such precipitations would produce. Probably the points shown on the diagram represent rates somewhere between 90% and 100% of maximum possible precipitation rates.

The discussion of the theoretical determination of storm rainfall constitutes an interesting introduction to a complicated meteorological problem. Although some items involved in the suggested method of calculation are not at present susceptible of accurate evaluation, the general method of attack seems logical and the continuance of such studies should lead eventually to a better general understanding of the problem. The application of Eq. 2 to some actual storm records and the publication of the results, including values of K, v, and W_E, would constitute a valuable addition to the paper.

W. G. HOYT,[6] M. AM. SOC. C. E.—In summarizing the progress made in one phase of hydrometeorology during the ten years since his earlier study in 1934 (29), Mr. Bernard has performed an excellent service to the engineering profession. In 1934 no attempt was made to answer the question as to whether or not the transposed storm was a "limiting" storm. The principal question raised at that time by the advising committee of hydrologic experts was whether or not, with reasonable likelihood, the great storms could have shifted slightly within a region, to center in a critical position on the particular basin of interest. As a result, however, of the research studies and observations described by Mr. Bernard, the hydraulic engineer of 1943 not only can transpose storms with reasonable surety but can determine, at least theoretically, with the meteorologic information now at his disposal, the potential limits of storm precipitation.

Credit certainly should accrue to the personnel of the various government agencies who have worked on the interrelated hydraulic and meteorologic problems and to the Corps of Engineers who in many instances made funds available for such studies. Not to be forgotten is the engineering staff of the Miami Conservancy District who early organized storm data for flood studies.

On June 15, 1932, a special Society Committee on Meteorologic Data submitted a progress report (30) in which they concluded among other things that, as of 1931, "Research in meteorology by the [Weather] Bureau, particularly along the lines which are used by the Engineering Profession, has not kept pace with the growing importance or utilization of this type of data, nor with research in other lines of science, either pure or applied." One reasonably might conclude from the evidence of Mr. Bernard's paper that, as of 1943, the research in meteorology—especially as it relates to the engineer in flood problems—is outstanding.

---

[6] Hydr. Engr. (Prin.), Water Resources Branch, U. S. Geological Survey, Washington, D. C.

L. R. BEARD,[7] JUN. AM. SOC. C. E.—Considerable progress has been made during the past several years in developing the science of hydrology. Perhaps the most difficult and most interesting development concerns the relation of rainfall to flood flow. This newer feature promises to rival that development in both difficulty and interest.

Because of the value of resolving a variable into its more fundamental components, it is advantageous to deal with meteorological factors rather than with observed precipitation. A disadvantage of dealing with meteorological factors is that, as Mr. Bernard states (see heading: "Principles of Storm Transposition"), there is available "a scanty 8 years of reasonably adequate upper-air data." These data are of utmost importance in the quantitative determination of precipitation.

In replacing a general function such as flood flow by its several component functions—infiltration, absorption, evaporation, return flow, transpiration, snow melt, detention, siltation, air moisture, wind velocity, frontal activity, convective activity, cyclonic activity, etc.—it is primarily necessary to relate the various component functions properly. However, if advantage is to be gained by this replacement, the probable error of the result obtained by using the component functions should be less than the probable error of the result obtained by using the general function. With the probable error of the result of each component function known, the probable error of the combined result can be computed by the equation (31):

$$R = \left[\sum_{j=1}^{j=m} \left(\frac{\partial Z}{\partial z_j} \right)^2 (r_j)^2 \right]^{0.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which there are m component functions, and in which: R = probable error of the combined result; Z = the combined result expressed in terms of the component results; z = a component result; and r = probable error of a component result. The relation of runoff to the component factors is not often a simple differentiable function, and much simplification would be necessary in order to apply Eq. 3 mathematically. However, it should be noted that the probable error of the sum or difference of m quantities is equal to

$$r_m = \left[\sum_{j=1}^{j=m} (r_j)^2 \right]^{0.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4a)$$

and the probable error of the product of two numbers is equal to

$$r = [(z_1)^2 (r_2)^2 + (z_2)^2 (r_1)^2]^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots (4b)$$

---

[7] Asst. Engr., U. S. Engrs., War Dept., Los Angeles, Calif.

The important point to be made is that the possibility of evaluating one factor very accurately should not be interpreted to mean that the combined result is necessarily evaluated accurately. If the maximum possible rainfall could be evaluated with great accuracy, then the probable error of the maximum possible flood derived therefrom would be slightly greater, on a percentage basis, than the probable error of the maximum possible over-all runoff coefficient. In general, the function "runoff coefficient" expressed in terms of infiltration, snow melt, detention, etc., is less reliable than the "runoff function," since it is derived from the latter. However, the runoff-coefficient function may converge more rapidly than does the runoff function, for which reason it is questionable whether the maximum possible runoff can be determined more accurately from rainfall than from runoff. The method by which maximum accuracy is obtained must be selected independently for each case.

In the determination of a maximum possible value of a function such as wind velocity, the procedure is not entirely mathematical. In general, such a value is merely considerably greater than any observed value (this is substantiated by the fact that the value is referred to as "maximum probable" by many). It is true that, in most cases, one scarcely can imagine a larger value. However, one hardly could imagine the occurrence of the Republican River flood of 1935 prior to that time. When the determination of the many factors (component functions) is made by "engineering judgment," a suggestion that the accuracy of the combination be investigated may be looked upon as a bit farfetched. However, the accuracy may be evaluated in the same manner as the quantity with the same justification.

There is one other point to be considered which is somewhat related to the accuracy discussion. Spillway and other designs sometimes are based on the maximum possible or maximum probable flood. In these cases, maximum possible values necessarily are evaluated as low as judgment allows (in order that construction costs will not be prohibitive). Remote or hazy possibilities are discounted. As a result, since the value cannot be strictly designated as maximum possible, it often is called maximum probable. The best that can be said for such a quantity is that it is perhaps a very large quantity and that it is the result of a decision making a design possible. Such a decision might not have been made if a more definable quantity were demanded. In other words, it "gets the job done." The worst that might be said for such a quantity is that its use as a maximum possible value would cause the following:

(*a*) The engineer would use the value as a basis for his calculations and his judgment and, consequently, for his decisions, and therefore would not have a sound basis for such decisions; and

(*b*) The economic calculations would be in error because the possibility of a disaster resulting from an occurrence in excess of the maximum probable occurrence is neglected or overlooked.

One example of a remote possibility which is ordinarily neglected is the extreme condition of snow melt. Partly melted snow could exist as slush in such a state that a small amount of heat would release tremendous quantities of water. Under these conditions, the maximum possible runoff volume virtually would be unlimited.

In designating a region as being meteorologically homogeneous, certain exceptions must be admitted. The "western side of the Pacific Coast Ranges," for example, can be considered meteorologically homogeneous for air-mass qualities, upper wind velocities, and many other qualities, with certain toleration. However, one rightfully cannot transpose the rainfall data shown in Table 1(*j*) to any part of the region. This is because the areas in which these excessive rainfall amounts occurred are areas of normally high rainfall and cannot be considered to be on a par with other areas in the region. Opids Camp, Calif., has a normal seasonal rainfall of almost three times that of Los Angeles, Calif., which is about 15 miles distant. Almost invariably the rainfall at Opids Camp is two to three times that at Los Angeles. In the mountains north and east of Los Angeles, the area which could be said to have reasonably constant rainfall characteristics would be limited to a few square miles in extent. There are undoubtedly many other areas in the United States where simple storm transposition would be impracticable and where the condition of meteorological homogeneity is restricted.

The convective cell of Fig. 17 is the type of phenomenon which produces cloudburst or thunderstorm precipitation. The height of such a cell normally is limited by the depth of an instability layer and always is limited by the height of the tropopause. Experiments with fluids which are not exactly analogous to air have shown that the horizontal diameter of such a cell is on the order of three to four times the depth of the cell. As Fig. 17 shows only the rising half of the cell's cross section, the drawing of the descending (outside) part of the cell would complete a cell whose diameter, in this case, is about two times the depth. Condensation would occur in the part of the cell shown (ascending air), and rainfall therefore would occur below and near this part. Only very light rainfall, if any, would occur below the descending part of the cell.

The type of rainfall which is steady and almost uniformly distributed over large areas generally is associated with a cyclone and, often, a frontal system. The cyclone, which may extend far into the stratosphere, is a result of dynamic instability and cannot be classed as a convective cell, which is a result of thermal instability. Often, however, thermal instability is present in the vicinity of a cyclone, in which case both types of rainfall are superimposed.

Numerous other complicated factors should be considered before a meteorological analysis can be attempted for any area. Some admirable work has been done in this line by J. Bjerknes, consulting meteorologist, and by the Pacific Division Office of the U. S. Engineer Department at San Francisco, Calif. This work should be of considerable value for the formulation of a procedure of analysis.

ROBERT E. KENNEDY,[8] M. AM. SOC. C. E.—This paper should be read in connection with a similar paper (20) on the same subject—a bit more technical perhaps—by A. K. Showalter and S. B. Solot, who were mentioned by Mr. Bernard under "Acknowledgments." The writer is interested in the meteorological conditions described by these men as limits beyond which nature cannot go but which nature reaches quite frequently. If that is so, students of this subject are approaching the ultimate sources.

---

[8] Asst. Engr., U. S. Bureau of Reclamation, Denver, Colo.

The background of approach to the problem in both these papers is to divide it into three parts: First, there is the maximum amount of moisture available for precipitation that can be brought to the region under consideration; second, there is the maximum wind velocity in the region that will feed the moisture into the storm vortex; and, finally, there is the maximum time limit of duration of the disturbance.

The first step is comparatively simple. In 1939 Mr. Solot outlined a method (32) of ascertaining the water in a column 1 sq in. in area and some miles high. From this point it is a logical step to ascertain the precipitable water in a column of saturated air and to tie it to the dew point at the surface. This was done by Messrs. Showalter and Solot (20*a*).

The moisture is brought in by some maritime air mass and is spread out like a blanket over an area extending from its source region over the ocean. Studies of air mass movements account for the disturbances that develop in this blanket. The trigger action that sets off the storm is described in both papers; but, whatever starts it, the action itself results in a maelstrom of updraft turbulence fed by the energy of latent heat released when the moisture is precipitated. The updraft provides temporary storage for large quantities of the neighboring blanket of moisture fed in at high wind velocity.

Both papers represent this action by the same figure. This is Fig. 17 in Mr. Bernard's paper, which represents the typical maximum storm as extending vertically to near the stratosphere with about one third of its height indraft, one third updraft, and the top one third outdraft of that part that gets away. All the precipitable moisture does not finally fall out as rain.

Fig. 17 appears to be entirely empirical based largely on visual appearance, mainly as seen in the miniature model of a summer thunderstorm. It seems to be a concept that has been generally accepted for a long time.

The curve, W_E, of effective precipitable water as related to surface dew point is another empirical relation, justified no doubt because it works within the limits of the data from which it was derived.

The limits of the surface dew points are described by Messrs. Showalter and Solot. The upper limit is about 80° F, which is about the maximum possible over the ocean from which the moisture blanket originates. These investigators find that it will not become less than 50° no matter how far the moisture is carried inland.

Just how the maximum probable dew point for the season is derived for a particular region is not indicated, but the authors appear confident they have approached the ultimate. The reader is referred by Messrs. Showalter and Solot to the Sacramento report for discussion of that feature.

The second step in the procedure is to estimate the velocity of inflow. Local anemometer records yield information as to wind velocities near the ground. Velocities in the upper part of the lower one third of the cell representing inflow are derived from the records of temperature and pressure at the 5-km level in the rear of major storms. A complete survey of the extreme minimum temperatures and pressures at that elevation has been made and is being kept up to date, according to Messrs. Showalter and Solot, who state that the maximum rate of upper air inflow is assumed to be reached in most of the major outstanding storms (20*b*)—another ultimate. These men have outlined briefly the procedure involved to estimate the geostrophic wind velocity at that elevation.

The third and final step is to estimate how long the storm will last. Apparently, Messrs. Showalter and Solot failed to find meteorological relations that can be evaluated readily. Resort is made largely to the statistical procedure of the hydrologists in which depth of precipitation, in inches, is plotted against duration in time. Both papers show such curves.

The reasons given for making these studies are twofold. The maximum storm as developed statistically by the hydrologists may be larger than actually can fall from the skies. Messrs. Showalter and Solot do not cite any such instance but it would be interesting if they had. Second, these studies give some measure of control in storm transposition. At least one is less likely to transpose a storm entirely out of its meteorological region. Storm transposition does not seem to be encouraged by these men. Mr. Bernard uses it cautiously. It is being supplanted by area-duration-depth data.

L. K. Sherman,[9] M. Am. Soc. C. E.—One of the tests, as to whether the occurrence of the ultimate maximum storms presented by the author are within the realm of reasonable probability, is furnished by computing the runoff that such storms would produce. Such computed runoff per square mile of basin may be compared by analogy with the large range of recorded runoffs. In any event, it is the amount of the possible flood that is wanted. The storm is simply a means to estimate the flood magnitude.

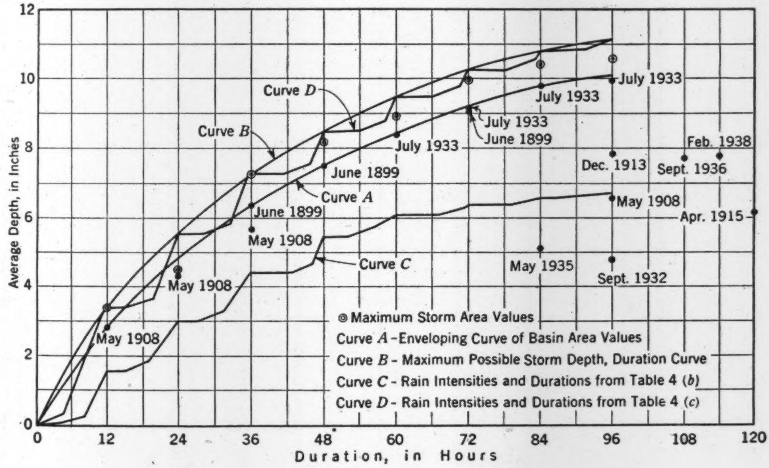

Fig. 23.—Revised Depth-Duration Curves, Red River Basin Above Denison, Tex.

	Duration, in Hours:									
24	Noneffective	4.45	4.45	4.45	4.45	4.45	4.45	4.45	4.45	35.5
25	Effective	7.1	4.6	3.5	2.5	2.1	1.4	1.2	0.6	23.0
26	Depth of noneffective rainfall, in inches	0.27	0.27	0.27	0.27	0.27	0.27	0.27	0.27	2.16
27	Average effective-rain intensity, i, in inches per hour	0.45	0.42	0.41	0.37	0.35	0.31	0.28	....	....
28	Basin runoff, in inches	1.72	1.02	0.73	0.44	0.32	0.13	0.08	0.01	4.45

When he was called upon to estimate the maximum possible flood from the Red River basin above Denison, Tex., the writer utilized the author's maximum design storm shown as curve K in Fig. 8. This depth-duration curve, drawn to a natural scale, with more detail, is shown in Fig. 23, taken from a report of the U. S. Weather Bureau (33). Curves C and D were plotted in Fig. 23 by the writer.

The derivation of runoff from this rain depth-duration curve B presents some problems not encountered in deriving runoff from an observed storm. The storm patterns, intensities, and durations of rainfalls are unknown in this case.

As a guide in deriving these unknown quantities, the writer utilized the data from the largest storm of record which fell on the Red River basin above Denison—the storm of May 21–25, 1908. The data derived from the records of this storm are presented in Table 4(*a*). The 4-day storm period was divided into eight periods of 12 hr. Each 12-hr period was computed as if it were a separate storm. In this way, cognizance was taken of the continuous changes in the position of storm intensities, areas wetted, and durations of effective, noneffective, and no rain.

In this 1908 storm, the point of maximum rain intensity started at Childress, Tex.; then proceeded to Hobart and Pauls Valley, Okla; thence south and west along the Red River back to Childress; and finally moved to Harrington, Okla., and Denison. The movement was always in a clockwise direction. The four highest spot rainfalls in the 12-hr periods were 4.29 in., 4.42 in., 4.27 in., and 4.39 in. There were forty-four rain recording stations in and about the basin, with four first-class stations outside. Mass curves of rainfall were made for most of the rain stations by the U. S. Weather Bureau. With a template set to the angle of f (Item 5, Table 4(*a*)), the writer derived the time durations of rains given in Items 6 and 7, Table 4(*a*). The weighted averages used in deriving runoff were obtained with Theissen's method. For moving storms the writer prefers this method to isohyetal maps. The averaged 12-hr amounts and durations in Table 4(*a*) actually represent a large number of downpours and lulls, varying from zero to very high intensities throughout the 12 hr. They are grouped into two classes: Effective and noneffective rain.

Table 4(*b*) assumes that the storm of May, 1908, covered the entire basin of 38,400 sq miles to the average depths covered on the wetted fractional areas found in Table 4(*a*). It further assumes that the ground has been wetted by antecedent rainfall so that its infiltration capacity has been reduced to f_c, the ultimate minimum capacity of the basin for the early growing season, in which the major floods have occurred. Durations of rain are kept as per the actual storm on the basin. The resulting rain amounts have been plotted as curve C in Fig. 23. The assumptions here made are conservative, as evidenced by the fact that the amounts of rainfall are under the 12-hr amounts given by the U. S. Weather Bureau, marked "May, 1908." These latter points represent amounts from the May, 1908, storm when transposed to its most effective position on the basin.

Table 4(*c*) is a computation based on the maximum rainfall depth-duration curve B of the U. S. Weather Bureau. This rainfall totals 11.1 in. average depth over the basin. This is more than twice the amount of the largest storm of record.

Tables 4(*a*) and 4(*b*) indicate that depths of noneffective rain, in the largest observed storm on the basin, followed fairly uniform averaged amounts in each of the 12-hr periods. The observed average intensity of all the noneffective rains at each of the stations on the basin was about 0.05 in. per hr or 0.06 in. per hr. The total period of noneffective rain in the maximum storm probably will be longer than that of 1908. How much longer is unknown. It is not reasonable to suppose that the maximum storm will have a total duration less than that of 1908. Any assumption of increase in the duration of noneffective rain will reduce the volume of runoff. Therefore, the writer has assumed that the average intensity of noneffective rain will be 0.06 in. per hr and that the duration will be 35.5 hr, the same as in 1908. This gives 35.5/8 = 4.44 hr for each period. At 0.06 in. per hr the depth of noneffective rain is 0.27 in. This appears in Item 26, Table 4(*c*).

Following the same line of reasoning, the writer has adhered to the total duration of effective rains (23 hr) as it existed in the largest storm of record. However, this value is subject to comparison with the resulting average intensities. The average effective-rain duration for a 12-hr period is 22.9/8 = 2.86 hr. Item 7, Table 4(*a*), and Item 16, Table 4(*b*), indicate that the effective rain durations are longer than the average for the larger rains and shorter than average for the lesser rains. Accordingly, the writer has prorated the average duration in the proportions of each given 12 hr of effective rain depth to the average depth. The average effective rain depth is 11.1/8 = 1.39 in. Prorating to derive Item 25, Table 4(*c*):

$$\begin{aligned} 2.86 \text{ hr} \times 3.4/1.39 &= 7.1 \text{ hr} \\ 2.86 \text{ hr} \times 2.2/1.39 &= 4.7 \text{ hr} \\ 2.86 \text{ hr} \times 1.7/1.39 &= 3.5 \text{ hr, etc.} \end{aligned}$$

The derivations of infiltration capacities f for the basin were made from a number of observed rainfall-runoff records including the 1908 storm.

Values of average effective-rain intensity for 12 hr over the basin were derived thus (using Table 4(*a*) as an example):

$$\frac{\text{Item 4} - \text{Item 8}}{\text{Item 5}} = i \text{ or Item 9}$$

Runoff from the basin in Tables 4(*a*) and 4(*b*) was derived by taking the sum of the rain excess on each Theissen subarea multiplied by its percentage of the entire area. Runoff in Table 4(*c*) was found thus:

$$\text{Item 22} - \text{Item 26} - \text{Item 25} \times \text{Item 23} = \text{Runoff or Item 28}$$

Runoffs, in cubic feet per second, were derived by the unit-hydrograph method; 12-hr distribution graphs were used against the eight derived depths of runoff in the sequence of their occurrence. In the cases where f_c was a constant, the sequence or order is immaterial.

The Red River basin above Denison includes two major streams which unite just above Denison. One is the Red River proper with a drainage area of 30,600 sq miles, and the other is the Washita with 7,700 sq miles. Hydrographs from several storms showed that peak from the Washita sometimes followed and sometimes preceded the Red River peak, thereby showing that synchronization of the two-peak flow was possible. Accordingly, separate unit hydrographs were derived for the Red and Washita rivers and the two combined to derive the ultimate possible peak flow.

The peak of the flood hydrograph, from the design storm (curve B, Fig. 23) at Denison, will be 1,500,000 cu ft per sec or 39 cu ft per sec per sq mile. This is based on the possible synchronization of the Red and Washita peaks.

The more probable peak flow, without synchronization, will still range from 1,100,000 to 1,300,000 cu ft per sec. The peak flow over a spillway, of course, will be reduced in accordance with available flood storage back of the dam.

The peak runoff of 1,500,000 cu ft per sec does not mean that the total volume of the maximum flood is increased. That volume remains the same whether the peaks synchronize or not.

In combining unit hydrographs from different areas, the distribution graph must be expressed in inches and not in percentages.

The writer is of the opinion that: (*a*) The author's "design storm" is what it purports to be—"the maximum possible storm"; (*b*) it should be used in the design of all structures which, in the event of failure, would involve large loss of life and property damage; (*c*) the values for runoff thus derived call for no additional factor of safety, since that factor has been cared for by the concatination of possible events; and (*d*) the author's "design storm" furnishes far more reliable limits than any data derived by statistical analysis. The latter, based on a long-time record, does furnish a possible check on the engineer's computations and may aid him in deciding whether a particular structure warrants the elimination of certain remote hazards.

C. H. EIFFERT,[10] M. AM. SOC. C. E.—Much new information has been collected in this field during the past few years, perhaps largely because of the increased interest in aviation. The U. S. Weather Bureau and Mr. Bernard are to be commended for the progress in this direction.

When the Miami Conservancy District investigations were begun about 1913, little information was available outside of the Weather Bureau records of precipitation, temperature, and wind movement. Therefore it is quite gratifying to note that what Mr. Bernard calculates to be the maximum possible storm that could occur, in the area where the 1913 flood actually did occur, agrees quite closely with what was decided on as the maximum possible when the Miami Conservancy District studies were made.

In connection with his calculations Mr. Bernard reaches the following conclusion (see heading, "Procedure in Developing the Maximum Possible Storm for an Individual Basin"): "* * * the March, 1913, storm rainfall could have been 28% greater or 128% of the observed depths."

The following paragraph is quoted from "Storm Rainfall of Eastern United States," Part V, *Technical Reports of the Miami Conservancy District* (34), under the heading, "Reasons for Choosing as Basis of Design a Flood 40 Per Cent Greater than that of March 1913":

---

[10] Chf. Engr. and Gen. Mgr., The Miami Conservancy Dist., Dayton, Ohio.

> "The extensive investigation of storms in the eastern United States leads to the belief that the March, 1913, flood was one of the great floods of centuries in the Miami Valley. In the course of three or four hundred years, however, a flood 15 or 20 per cent greater may occur. It is not believed that a flood will ever occur which is more than 20 or 25 per cent in excess of that of March 1913. There is a factor of ignorance, however, which should be provided against, and the only way this could be done was arbitrarily to increase the size of maximum flood provided for. If longer records were available a closer estimate could be made, but in planning works on which the protection of the Miami Valley depends, it was necessary to go beyond human judgment. This was done on all the other phases of the design, and it was believed that it would not be good engineering practice to stop at individual judgment on this phase. The planners of the project felt that they must be able to say that the engineering works are safe in every respect. For this reason provision was made for a flood nearly 40 per cent greater than that of March 1913. This is 15 or 20 per cent in excess of what is believed to be the greatest possible flood that will ever occur."

In this discussion the writer cannot refrain from referring again to the possibility of Weather Bureau records being kept in such a way as to be more useful and less difficult to interpret by engineers making hydrological studies. The principal Weather Bureau stations record their precipitation from midnight to midnight; many observers take evening readings; many others make their observations in the morning; and some are recorded from noon to noon. When storm rainfall maps and studies involving such records are prepared, it is often very difficult and sometimes impossible to determine on which day a considerable part of the rainfall actually occurred. This is particularly true in connection with storms of short duration. Why would it not be possible to change this system so that all readings are taken at approximately the same time of day? Most observers could make either morning or evening observations, and those who could not read at the required time could be replaced gradually. Obviously it is not practical for the ordinary observer to make his observations at midnight. However, the midnight stations have recording gages so that their records are adaptable to any time and could be used in connection with either morning or evening records. Originally, the Weather Bureau rainfall observations were not intended for this purpose, being thought of mainly in connection with agriculture. The extensive use of these records in recent years by engineers and hydrologists would seem to be of sufficient importance to justify such a change.

On the first page of his paper, the author refers to time-area-depth values for about 150 storms. Throughout the remainder of the paper these values are referred to as area-duration-depth values. On the Miami Conservancy District work the term time-area-depth was used. Although the word "duration" is slightly more specific in its meaning, either expression is readily understandable. "Time-area-depth" would seem to this writer to be preferable for the sake of its euphony and greater ease of oral expression.

GAIL A. HATHAWAY,[11] M. AM. SOC. C. E.—Excellent progress is being made in this extremely important phase of flood control as well as in connection with all problems involved in the development and utilization of water resources in the United States. The paper is a comprehensive report of this progress. The investigation of the meteorological and hydrological aspects of major storms by the Hydrometeorological Section of the U. S. Weather Bureau has furnished the engineer with a much clearer picture of the probable limiting rates of storm rainfall.

---

[11] Hydr. Engr., War Dept., Office, Chf. of Engrs., Washington, D. C.

In discussing the general subject of storm studies it may be of interest to review briefly some of the events leading to the present work of the Hydrometeorological Section of the Weather Bureau which has proved so valuable in the flood control work of the Corps of Engineers. Shortly after the great storm of May 30–31, 1935, in the headwaters of the Republican River basin, the writer was engaged on a study to determine a spillway design flood for the Kingsley Dam (previously the Keystone Dam) on the North Platte River near North Platte, Nebr. The question immediately arose as to whether it would be reasonable to expect a storm similar to that of May, 1935, to occur over the drainage area of the North Platte River above Kingsley Dam, which is about 150 miles north of the Republican River headwaters. At that time E. J. Minser (chief meteorologist, Transcontinental and Western Air, Inc.) and the writer made a meteorological analysis of the storm to ascertain the feasibility of transposing it to the North Platte River drainage area. After careful study the conclusion was reached that there was no good reason, from the meteorological or physiographical viewpoint, why the storm could not have occurred over the North Platte basin above Kingsley Dam. Similar meteorological studies were made by the writer in 1935 and 1936, while he was employed by the U. S. Engineer Department, for the Sardis Dam on the Little Tallahatchie River in Mississippi, the Bluestone Dam on the New River in West Virginia, and the Possum Kingdom Dam on the Brazos River in Texas.

During the summer of 1936, arrangements were made by the Corps of Engineers for the assignment to the Office, Chief of Engineers, of the late Wilson Reed, Jr., to conduct meteorological studies of selected river basins. However, the demand from the field offices of the Engineer Department for meteorological studies was so great that, later in 1937, a group was set up in the Weather Bureau to make the studies. As stated by the author, this group had been working for, and in cooperation with, the Engineer Department in the review of the meteorological aspects of storms and the determination of maximum storm rates for specific drainage basins.

The first line of attack in any hydrological problem involving runoff is a thorough analysis of rainfall data. The author has reviewed the historical background of storm records and the early investigation and analysis of storm rainfall data. The early studies of storm rainfall are extremely valuable, but the present-day hydrologic technique requires that rainfall intensities be broken down into periods of less than 24 hr. Analysis of a large number of major storms in the United States shows that the maximum rainfall intensities usually occur in periods of 12 hr or less, interspersed with periods of minor rainfall rates. It is considered essential, therefore, that maximum rainfall quantities be determined for periods of 6 hr and in some cases for shorter time intervals. Because of the importance of a thorough analysis of storm rainfall the Engineer

Department, in 1937, organized a program for the study of several hundred major storms covering the entire continental area of the United States. The program also includes the analysis of current storms of major proportions. These recent storm studies are extremely valuable because of the existing network of recording rainfall stations, and the large number of upper-air observations made by means of pilot balloons and "radiosondes."

The study of major storms by the division and district offices of the Engineer Department has been divided into Part I and Part II. Part I of the study consists of the compilation of basic precipitation data, preparation of mass rainfall curves, and isohyetal maps. In addition to published records of the Weather Bureau, Part I includes all available precipitation data and miscellaneous information on storms obtainable from the manuscripts of original records, files of municipal agencies, newspapers, testimony of witnesses, and similar sources. In the event of a major storm, representatives of district offices conduct a field survey in the areas of excessive rainfall to obtain a record of rainfall measurements secured by local residents. The location and method of obtaining these "bucket" or "washtub" records are analyzed carefully on the ground and every effort is made to classify them as to their reliability. Part I of the study, assembled and organized by the various district offices, is reviewed by the Hydrometeorological Section of the Weather Bureau and the mass rainfall curves are correlated with the meteorological analysis of the storm.

Upon completion of the review by the Hydrometeorological Section, Part I is returned to the originating district office for completion of Part II of the study. The preparation of Part II involves the following steps:

(*a*) Preparation of the final total-storm isohyetal map based on the selected storm period, or delineation of zones on the isohyetal map and grouping of rainfall stations by zones;

(*b*) Tabulation of contemporaneous rainfall quantities as scaled from mass rainfall curves, for periods usually increasing by 6-hr increments;

(*c*) Tabulation of absolute maxima rainfall quantities for durations of 6, 12, 18, and 24 hr for stations within the zones of excessive rainfall intensity;

(*d*) The computation of mass rainfall curves representing the average depth of rainfall over selected areas of the storm; and

(*e*) The computation of maxima duration-depth-area data for various combinations of zones.

The final isohyetal map showing the zone subdivisions and the duration-depth-area curves for a typical major storm are shown in Figs. 24 and 25. In this case, mass rainfall curves were prepared for stations underscored with a single line; and recording-gage records were available for stations underscored with a double line. In most cases, rainfall values of less than 3 in. were interpolated from published records without constructing mass curves. Hence they are approximate. For the purpose of clarity, the odd numbered isohyets above 4 in. have been deleted from the isohyetal map in Fig. 24. All of the isohyets (that is, 1 to 21 in.) were used in computation of the depth-area data in Fig. 25. Pertinent data sheets similar to that shown in Fig. 26 are prepared

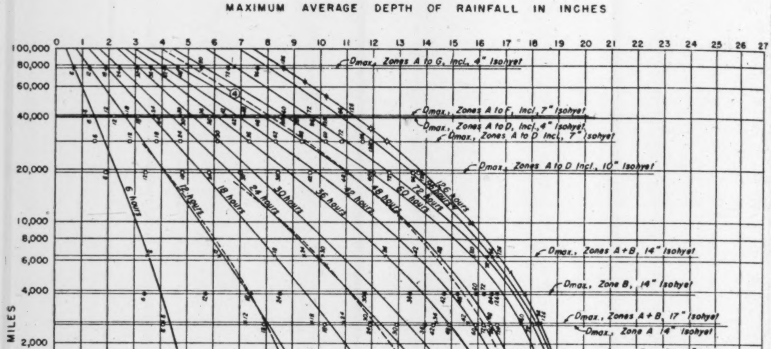
for each storm study for use of the various district offices in determining whether the completed storm studies have a direct bearing on problems in their respective offices. The sheets also serve as an index to the data assembled in each study.

At the beginning of the storm study program, 1,350 storms were assigned to district offices of the Engineer Department. However, it is not expected



Explanation

"D_{max}, Zones A + B, 14" isohyet" refers to maximum depth-duration values computed for the area within zones A + B and the 14 in. isohyet.

Curves shown by solid lines represent final maximum depth-area curves.

Depth-area curves shown in broken line (- - -) were computed (for comparison only) by planimetering isohyetal maps for following periods. (1) 12 hr ending 1 A 24, (2) 24 hr ending 7 A 24, (3) 48 hr ending 7 P 24, (4) 48 hr ending 1 P 25.

Plotted points represent maximum average depth of rainfall, over the area designated, within the number of hours indicated by figures beside the points.

Identical legends were used for all depth-duration curves within the same zone or combination of zones.

FIG. 26.—PERTINENT DATA SHEET OF STORM STUDIES

that all of the storms under study will be completed to the point of computing 6-hr rainfall quantities and preparing duration-depth-area data for short-time intervals. Only the major storms in each section of the United States with critical rates for different intervals of time will be analyzed completely.

In connection with the presentation of duration-depth-area data by the author in Table 1 it appears desirable to point out that the depth-area relationships for the August 6–7, 1935, storm in Ohio, and the July 4–5, 1939, storm in Kentucky were derived largely from unofficial or so-called "bucket" observations; but no footnote has been added to indicate that the results were obtained from other than official observations. A brief footnote in such instances, concerning the source and relative accuracy of the data, would seem appropriate.

L. STANDISH HALL,[12] M. AM. SOC. C. E.—A valuable summary of modern developments in meteorology for application to flood flow estimating is contained in this paper. In general, the rôle of meteorology as applied to flood flows is in the determination of maximum rates of precipitation. The analysis must include time-area-depth studies to cover drainage areas of various sizes, and for this purpose Table 1 contains valuable data. Having made similar studies for specific storms the writer can appreciate the time and effort necessary in the compiling of such a table.

Fig. 7 is of great interest in developing an upper limit for maximum rainfall rates. As pointed out by the author, before one can arrive at the maximum rate for a specific area the physiographic influences particular to the region in which the basin is located must be considered. As an example, on the western side of the Coast Range in the vicinity of San Francisco, Calif., a rainfall rate of 1 in. per hr can be expected once in 25 years. Whereas a rainfall rate of 2 in. per hr would occur less frequently than 100-yr intervals. This rate is materially below the world's record of between 10 and 15 in. in 1 hr, and the use of a rate in excess of 2 in. per hr for the San Francisco area would be extravagant. On many structures the use of an even smaller "design" flood would be justified when the damage caused by the rare flood would not justify the added expense of the larger structure.

Storm transposition must be used with caution in regions where orographic influences are a predominant factor. The author has not stressed this feature sufficiently. The report of the Miami Conservancy District focuses attention on this point (1*a*):

> "In beginning this investigation it was uncertain what geographic limits should be set to obtain the largest amount of useful and pertinent data. These limits at first were assumed to include the entire United States, but during the progress of the investigation it became apparent that rainfall conditions in the Western part of the country differ radically from those in the Eastern part, that by limiting the area to that east of the 103d meridian, running through Texas, Colorado, Nebraska and North and South Dakota, no applicable data would be excluded."

Under the heading, "Regions of Meteorological Homogeneity," the author has recognized the variation in rainfall intensity in California by including portions of the state within four areas (Nos. 1, 2, 3, and 7). Even with this subdivision two important areas are omitted, namely the west side of the Sierra Nevada and the east side of the Sierra Nevada. Marked variation of rainfall intensity created by the rugged topography could be cited within the boundaries of these six areas.

---

[12] Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

With reference to the contribution of snow melt to storm runoff, the author's statement, that the flood hazard increases when the snow accumulates beyond normal depth and water content, must be modified with respect to the Sierra Nevada in California. For those unacquainted with this area it should be noted that the depth of annual snowfall is not exceeded in any other part of the United States, and during the period from January to March the normal depth of snow on the ground above El. 6,000 is from 6 ft to 10 ft. Heavy snow cover over the high Sierra acts as an influence in the suppression of flood conditions.

Rainfall over the mountain areas of the Sierra is not the only element increasing floods of large magnitude in the Central Valley of California, but air temperature during the storm and the amount of snow on the ground prior to the storm are contributing factors. If cold storms have placed snow at low altitudes which is followed by a warm rain, the danger of a large flood is greatly increased. The greatest flood danger occurs when there is less than 4 ft of snow over all or a large part of the drainage area. After the snow has accumulated to a greater depth, warm rain serves only to compact the snow but does not yield much runoff. When the depth of snow is less than 4 ft, and particularly when it is less than 2 ft, a warm rain and the accompanying warm air currents can frequently melt all of the snow. Observations have been made at an elevation of approximately 4,000 ft near Calaveras Big Trees, Calaveras County, California, of a depth of 4 ft of snow being melted entirely between weekly visits during a period of high temperature and warm rains. The large flood of December, 1937, was the result of a warm rain at a time when there was less than 2 ft of snow over a large portion of the Sierra (35). The same conditions occurred in 1928 during the large flood of that year (36). Prior to the warm rain in the latter part of March, a maximum of only 4 ft of snow had been accumulated on the higher altitudes of the watersheds. This rain melted most of the snow, with the result that very large floods occurred. Prior to the flood of 1928, there was a general belief among engineers that a major flood could not occur in a year of subnormal runoff. The reports available indicate that, in the record floods of 1861–1862, there was snow at very low elevations in the foothills prior to the storm. There were really three major floods in that year; one in December, 1861, and two in January, 1862, when warm rains melting snow augmented the runoff (37). To be sure, rains of unprecedented volume occurred at the same time. Without citing further examples, it can be stated as a result of observations of the snow-pack and meteorological conditions accompanying large floods in the Sierra that, whenever the snow is at low altitudes in the foothills and a warm rain of great intensity occurs, these are the conditions that produce the maximum flood runoff.

The procedure outlined by the author in developing the maximum possible storm for an individual basin offers a new approach to this problem of applied hydrology. With proper modifications based on the characteristics of individual basins it should yield dependable estimates of maximum flood flow. In addition to precipitation and depth of snow on the ground there are many other factors that have a very marked influence on volume of flood flow to be expected from a specific rate of precipitation. These factors for the most part are outside of the scope of the paper.

MERRILL BERNARD,[13] M. AM. SOC. C. E.—Mr. Gilman raises the natural doubt that the maximum storm necessarily produces the maximum flood. The writer's definition of the ultimate or maximum storm will be found to qualify magnitude in considering the principal exterior influences on floods—the snow-melt contribution to runoff; the loss to flow volume, infiltration; and the loss to peak flow, retardation. Perhaps it would be better to modify still further the definition by referring to the "effective" maximum storm. It is more important to note the differences in net effect between storms producing equal volumes of rainfall, in which case differences in distribution through time and over area result in flood hydrographs of varying shape and peak discharge. The apparent inability to sustain excessive intensities over any but relatively small areas would indicate the impossibility of experiencing concurrent maximum precipitation over the watersheds of every tributary of a basin except in the case of a very small one. The critical synchronization of tributary flow, like the most critical storm rainfall pattern, will depend largely upon the characteristics of the particular basin. On the larger basins, synchronization is involved in the direction of storm movement. This is not to be confused with the so-called "storm track" comprised of the trace of movement of an area of low barometric pressure. In certain localities physiographic controls will establish a fairly stable régime in the direction of movement of the "rain front" of "rain pattern." More often, the direction is fortuitous, depending usually on the orientation of an extended quasi-stationary front and the timing of energy releasing "waves" along it. When physiographic influences do not predominate and the region of homogeneity is sufficiently extensive to permit the transposition and superposition of storm maps to and upon basin maps, all, or the greater number, of the steps given in Table 5 are necessary to the synthesis of the flood hydrograph.

Mr. Jarvis' particularly comprehensive discussion warrants far more consideration than can be given to it in these closing paragraphs. His questions in regard to the apparent inadequate values of W_E, effective precipitable water, are answered in references (2), (3), and (38).

Mr. Hoyt has referred to the progress report (30) of the special Society Committee on Meteorological Data. This piece of constructive criticism, to the writer's knowledge, has contributed much in guiding the Weather Bureau to its present important place as a source of engineering data. However, in retrospect, a principle in democratic evolution seems to have revealed itself; namely, the need must be demonstrated before fulfilment is made possible through financial support. Engineers have always wanted more precipitation data. The Weather Bureau (on appropriations of less than 5¢ per capita) was trying to provide them; but it took the demonstrated needs of flood control and soil erosion prevention to bring about the approval of Congress for the establishment of a network of nearly 3,000 recording (intensity) rainfall stations, several hundred badly needed stream discharge stations, and a score of field and indoor laboratories—all now playing important rôles in engineering programs.

---

[13] Hydrologic Director, U. S. Weather Bureau, Washington, D. C.

TABLE 5.—STEPS IN FLOOD HYDROGRAPH SYNTHESIS

No.	Step	Means of determination
1	Maximum storm volume	Total isohyetal map; area-volume relations
	Variation of Rainfall Depth—	
2	With time	Mass curves of rainfall
3	With duration	Depth-duration relations
4	With area	Depth-area relations
5	Distribution of rainfall depth over area	Isohyetal pattern, actual or synthetic
6	Critical time increment	Equal to or multiple of basin's concentration period
7	Critical time pattern	Arrangement of increment depths in critical time order
8	Maximum runoff volume	Superposition of total storm to give greatest volume of runoff under minimum loss conditions, to include the snow-melt increment when appropriate
9	Critical concentration of runoff	Superposition of storm increments to give greatest concentration of runoff in critical period
10	Critical synchronization of tributary flow	Progressive routing of tributary flow to disclose critical storm pattern and position
11	Maximum flood peak	Most effective combination of conditions for critical concentration of runoff and critical synchronization of tributary flow

Mr. Houk's comments on the distinction to be made between the maximum storm and the maximum flood emphasize those of Mr. Gilman. In general, the magnitude of storm and flood is of comparable order as the upper limits are approached. On small watersheds, rainfall must be expressed in terms of intensity for short periods. On large basins the volume of rainfall produced by an extensive storm will determine the magnitude of the resulting flood. In the former case, there will be a considerable fluctuation in ground surface effects, thereby disrupting the frequency relations between rainfall and the flood. In the latter case, initial rains will have reduced infiltration rates and will have provided sufficient water to occupy pondage and channel storage fully. Thus, the resulting flood will bear a far more consistent relation to storm rainfall than the rainfall of a brief storm over a small area.

The difficulties in determining storm rainfall over a prescribed basin through the solution of an equation of flow are partly revealed through an analogy in which the problem is to determine the deposition of suspended material in a silt laden stream throughout a reach in which the slope has been abruptly flattened. The flow is confined within an unyielding channel of fixed dimensions, and all the principal factor values are determinable, including the volume of deposited material and the residual of silt which leaves the reach at its outlet. In the equation of moist air flow, adequate means for measuring and giving quantitative expression to the comparable variables are largely lacking. The imaginary boundaries of the flow channel beyond the assumed inflow section have no assurance of reality. The residual moisture leaving the basin is not subject to measurement. Improved instrumentation and a more dense upper-air observation network can be expected to overcome most of these deficiencies.

It is fairly simple to determine the prevailing direction of inflow and, therefore, the basin constant K. Gradient winds can likewise be estimated with fair accuracy. The value of R can be found by planimetering the isohyetal map. It is not always possible, however, to disassociate v and W_E in actual storms. This does not invalidate the basic method of computing the maximum rainfall amounts since, for the physical upper limit, it would be necessary to assume that these two factors combined at their respective maximum effectiveness. It is not altogether logical to combine them at their physical upper limits because they are not completely independent.

In order to develop and maintain maximum velocities (which increase with height and, therefore, must be integrated throughout the depth of the inflow layer to provide maximum rates of inflow), there must be steep gradients of temperature as well as of pressure. At the same time the maximum moisture charge must necessarily be contained in a broad tongue of moist air characterized by the maximum possible saturation temperature at all levels. Also, the moisture charge must be horizontally isothermal throughout the full width of the tongue. Thus, the introduction of a temperature gradient automatically places limitation on the moisture charge.

Mr. Houk's suggestion that values for K, v, and W_E for the outstanding storms of record be published strikes a note of accord among all engineers interested in hydrometeorology. An illustration (38) is given in the case of the Sacramento River Basin where the principal lifting agencies providing the mechanism for producing rainfall are the Coastal Ranges and the Sierra Nevada. Since these barriers remain stationary, the problem of determining rainfall amounts through computation is somewhat simplified. The Point Reyes (Calif.) station was found to be representative for inflow wind velocities, and the dew points at San Francisco (Calif.) were used as an index to the moisture charge of the inflowing air mass. It was possible, therefore, to complete the computations of rates of rainfall by use of the basic formula, $R = \int K\, v\, W_E\, dt$ (see Eq. 2). Fig. 27 compares the theoretically computed average depths of rainfall over the basin with the observed depths obtained by planimetering isohyetal maps. Fig. 28 shows a comparison of the computed and observed time-intensity patterns for the storm of February 25–29, 1940.

The writer can agree with Mr. Beard in his principles of relative accuracy, the validity of which must await the time when observations of the variables he has enumerated have covered a period sufficiently long to have statistical significance. Engineers are now merely groping toward a state of knowledge that will ultimately introduce reasonably precise procedures into hydrologic design. In the meantime, efforts to refine the knowledge on any one of the factors in the sequence of events from the "meteorological storm" through the "hydrologic storm" to the culminating flood would seem warranted.

The designation of "maximum possible" to the storm values discussed in the writer's paper has the intended meaning that such values can be approached but not exceeded, and therefore can be considered only as the asymptotic limit of the magnitude-frequency curve. As Mr. Sherman has stated, such values should not be the basis for design in any except the case where social and psychological considerations dictate security beyond economic justification. In any case, it would seem as much an advantage to the flood control designer to know the upper limit of magnitude of his major factor, the storm, as it is to the structural designer to know the ultimate strength of his materials.

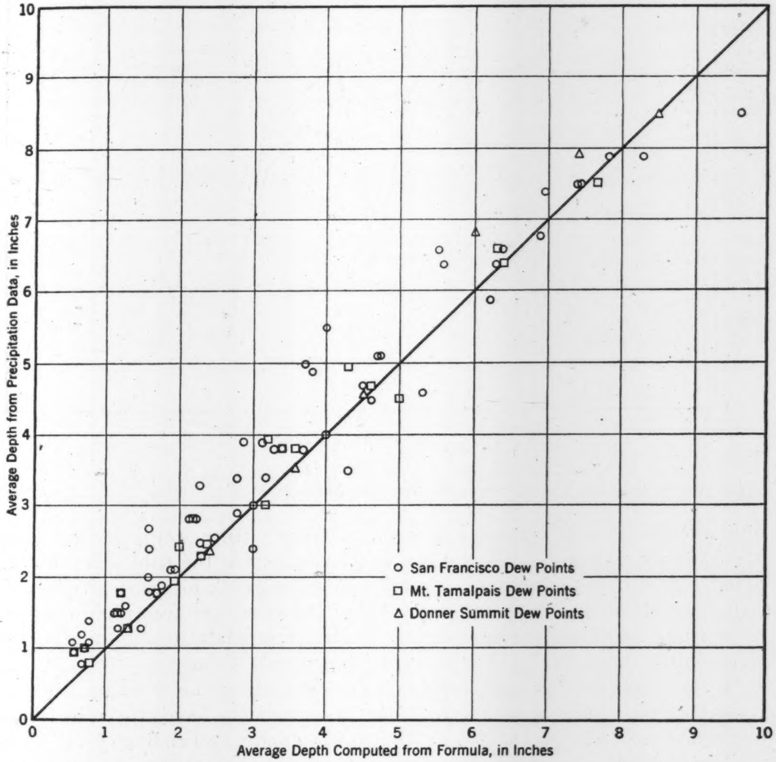

FIG. 27.—AVERAGE PRECIPITATION DEPTHS OVER TOTAL BASIN

The criticism of listed regions of meteorological homogeneity, particularly as the basis for justifying storm transposition, is readily admitted. Apparently, there is a compensative circumstance in certain mountainous areas where orographic controls so stabilize the rainfall régime that the seasonal pattern can be used as a guide to the distribution of storm rainfall over a large basin. The opinions of Messrs. Beard, Kennedy, and Hall have not overemphasized the cautions to be observed in storm transposition.

The writer is indebted to Mr. Kennedy for his review of the work of Messrs. Showalter and Solot (20). The theoretical determination of storm rainfall could be given only a limited place in the original paper.

It is hardly correct to say that storm transposition is being supplanted by area-duration-depth data. The designer will always resort to the simple expedient of superimposing storms over basins wherever homogeneity of rainfall régime exists. Values taken from area-depth curves are meaningless until they have been expressed as areal patterns—either actual or synthetic. Mr. Eiffert's reference to the apparent inconsistency in the title of Table 1 is noted. Area-depth curves constructed on a single graph for successive cumulative periods of time from the beginning of the storm are accurately referred to as time-area-depth curves, whereas those for separate durations, with no common beginning time, are more appropriately called duration curves.

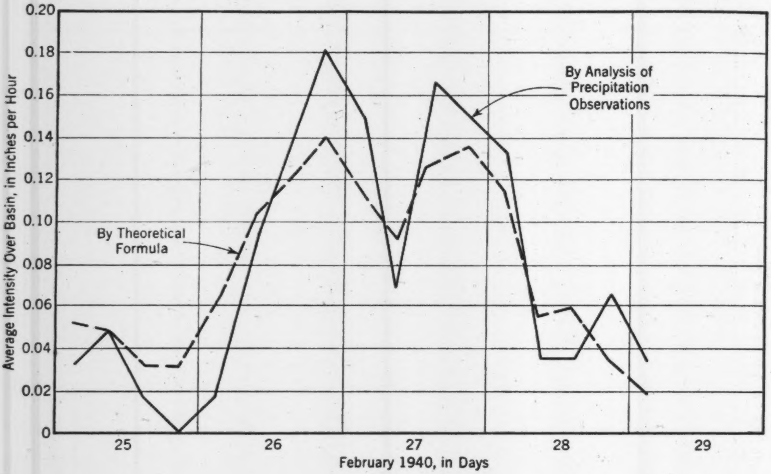

FIG. 28.—COMPUTED PRECIPITATION INTENSITY AVERAGE OVER TOTAL BASIN; STORM OF FEBRUARY 25–29, 1940

In the work of the Hydrometeorological Section of the Weather Bureau, it has been found that the staggered hours of observation have proved blessings in disguise, disclosing as they do the times of beginning and ending of rain (39).

Mr. Hathaway has made a particularly valuable contribution to the paper in illustrating the steps toward design objectives beyond those involving meteorology. That pertinent storm data will ultimately be made available in the concise terms characteristic of the Corps of Engineers should be appreciated by the civil engineering profession.

Paper No. 2213

APPLICATION OF SOIL MECHANICS IN DESIGNING BUILDING FOUNDATIONS

By A. Casagrande,[1] Assoc. M. Am. Soc. C. E., and
R. E. Fadum,[2] Jun. Am. Soc. C. E.

With Discussion by Messrs. Jacob Feld, Leonard Zeevaert, Gregory P. Tschebotarioff, Guthlac Wilson, W. H. McAlpine, Karl Terzaghi, D. P. Krynine, O. G. Julian, A. A. Eremin, D. M. Burmister, Abraham Woolf, Lazarus White, George L. Freeman, Soil Mechanics Committee of the Los Angeles Section—Trent R. Dames, Chairman, and Frederick J. Converse, Sterling S. Green, and Paul Baumann—and A. Casagrande and R. E. Fadum.

Synopsis

The first part of this paper reviews the causes of building settlements, and summarizes what soil mechanics has to offer as a basis for the design of building foundations. In the second part are described the foundations of two large office buildings in Boston, Mass., which were designed specifically for the purpose of reducing total and differential settlements to a tolerable amount. The settlements of these buildings are compared with those of other large buildings designed without the use of soil mechanics. The methods of reducing existing differential settlements are not discussed. The success of any method such as underpinning, the application of additional load to the lighter sections of a structure, the provision of continuous jacking arrangements, or the method of "bleeding" the underground by means of borings adjacent to and under those parts of a structure that have not settled are dependent on accurate observations of the behavior of the structure which is to be remedied.

Introduction

Although problems dealing with building settlements may be relatively simple as compared with other problems in soil mechanics, knowledge of soil properties is not yet sufficiently developed to permit an accurate solution even of this problem. It must be kept in mind that, in general, even the most

---

Note.—Published in November, 1942, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Prof., Civ. Eng., Harvard Univ., Cambridge, Mass.

[2] Instr. in Civ. Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass.

elaborate underground explorations do not disclose a complete picture of the soil conditions. Therefore, the results of a settlement analysis, as well as of most problems in applied soil mechanics, should be expressed by a range which includes the possible limits of all factors entering the computations. A clear discussion of the possible variations of each factor should be presented to facilitate a final decision by those who use the information for design purposes. It cannot be emphasized too strongly that the correct application of the results of such an investigation to the design of earthworks or foundations will, in addition to a thorough knowledge of soil mechanics, always require experience and judgment.

Differences Between Soils and Structural Materials.—The deformation of soils, even under small loads, is much larger than that of steel or concrete. Furthermore, the deformation of many types of soils does not occur simultaneously with the application of a load; it develops in the course of time. Therefore, one may not be aware of a dangerous situation until a building begins to crack many years after it has been built.

Another difference between structural materials and soils resides in the fact that in the former deformation is chiefly a result of a change in shape. In soils, however, deformation is the result of both a change in shape and a change in volume. In some problems, and in particular problems dealing with the settlement of buildings resting on clay, the deformation due to change in volume of the underlying soil layers is usually much more important than the deformation due to change in shape.

Much confusion and harm have resulted in the past from the belief that a satisfactory allowable load for a soil can be obtained by reducing the failure load, derived from surface-loading tests or pile-loading tests, by a liberal factor of safety. The resulting stresses will not produce rupture of the soil. There is no assurance, however, that these "safe" stresses in the soil will not produce objectionable or dangerous settlements.

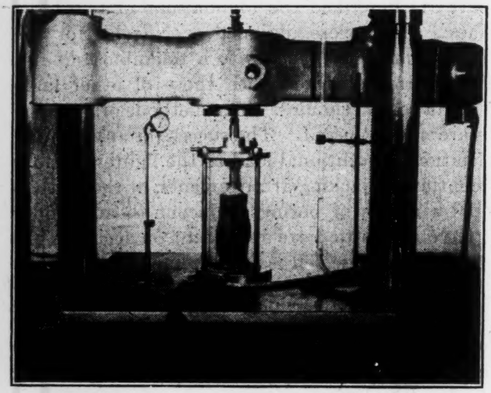

FIG. 1.—TRIAXIAL COMPRESSION APPARATUS.

SOIL PROPERTIES RESPONSIBLE FOR SETTLEMENTS

General. — Since, for practical purposes, soils possess no tensile strength, only the deformation characteristics resulting from compression forces are of interest. Therefore, the principal testing methods are designed to subject soil samples to compression. Theoretically, it should be possible to determine all the stress-deformation characteristics from so-called "triaxial compression tests." In this type of test the principal stresses can be varied at liberty, thereby producing any desired combination of normal and shearing stresses within a sample. Actually, the only practical type of triaxial compression test apparatus thus far developed is one in which two of the principal stresses are kept equal. These stresses are produced by the pressure of a liquid surrounding a cylindrical specimen (Fig. 1). If such a compression test is made without this liquid pressure, the test is called an "unconfined compression test." This type of test is similar to cylindrical compression tests used in concrete testing. In a third type of compression test, which is of particular importance in the testing of clays, the specimen is confined laterally in a metal ring and is compressed between two porous plates. In this "confined compression test" (which is also called a "consolidation test"), the lateral displacements are prevented entirely, and one measures only the relation between stress, volume, and time.

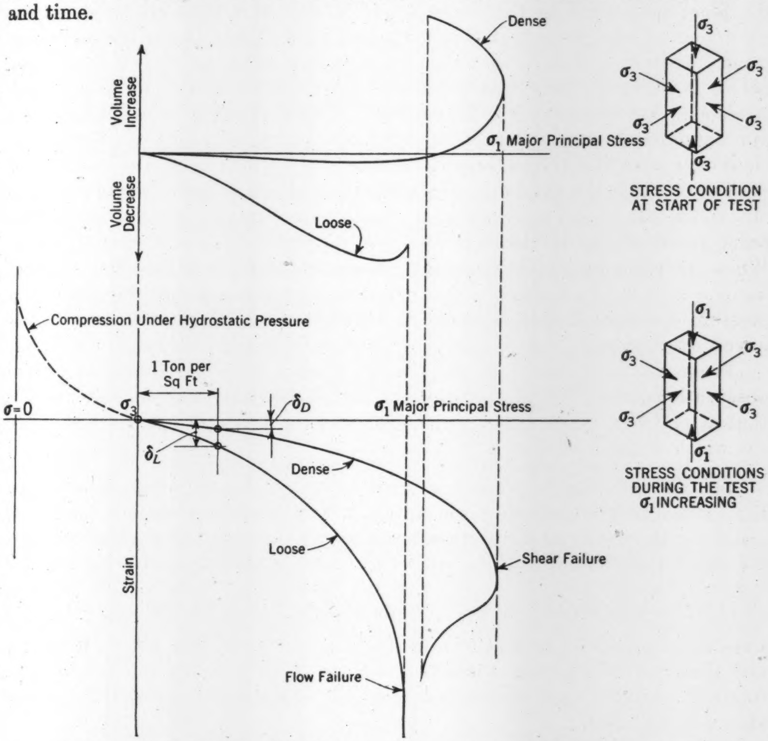

FIG. 2.—TYPICAL STRESS-STRAIN AND STRESS-VOLUME CHANGE CURVES FOR SAND

Notation.—The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

Stress-Deformation Characteristics of Cohesionless Soils.—When a sample of sand is tested in triaxial compression, starting, for example, from a hydrostatic stress condition, and then one of the principal stresses is increased until failure occurs, stress-strain and stress-volume change curves of the type shown in Fig. 2 are obtained. A loose sand decreases in volume, whereas a dense sand expands during loading. Although this behavior is of great importance in connection with the question of stability of dams consisting chiefly of fine-grained or medium-grained sands, it is of limited interest in problems attending building construction. Buildings resting on loose fine sands or inorganic silts are likely to undergo sudden settlements if the underlying soil is disturbed—for example, by heavy pile-driving operations in adjacent building areas. Most sand deposits, however, are sufficiently dense that no such dangers exist.

The chief concern is with ordinary deformation under stress and its effect upon the distribution of soil reactions. It can be noted from Fig. 2 that an increase in stress of (for example) 1.0 ton per sq ft produces a larger strain in the loose sand than in the dense sand. If the two tests are repeated on specimens of the same material, subjected to different intensities of minor principal stress, one finds that the strain corresponding to $\sigma_1 - \sigma_3 = 1.0$ ton per sq ft changes approximately in inverse proportion to the minor principal stress σ_3. Furthermore, it is found that the shear strength of sands increases approximately in direct proportion with the minor principal stress. The coefficient expressing this proportionality is called the coefficient of internal friction.

The fact that the resistance to deformation, as well as the ultimate strength, of a cohesionless solid increases approximately in direct proportion to the confining pressures can be demonstrated easily by placing sand in a rubber bag. When the air is evacuated from the interior of such a soft bag, the contents become as hard as a brick. The evacuation of air subjects the sand to a pressure corresponding in intensity to that produced by approximately 20 ft of soil overburden.

From consideration of these physical characteristics of sands, and from observations, the following conclusions, applicable only to noncohesive soils that extend to a depth below the loaded area for a distance at least equal to the width of the loaded area, may be drawn:

(*a*) The intensity of pressure exerted on a rigid, loaded area supported on the surface of a cohesionless soil varies in such a manner that a maximum occurs at the center and no pressure occurs at the edge. For small footings for which the product of the width of the footing and the unit weight of soil ($b\,\gamma$) is small in relation to the average unit load on the footing $\left(p = \dfrac{P}{A} \right)$, the pressure diagram is parabolic in shape, as shown in Fig. 3(*a*). When $b\,\gamma$ is of the same order of magnitude as $p = P/A$ (which is usually the case for large footings, or for a rigid foundation mat), the diagram of soil reactions is as shown in Fig. 3(*b*).

(*b*) As the depth of a rigid, loaded area beneath adjacent ground surface is increased, the soil reactions change until the intensity of pressure is nearly uniform, as shown in Fig. 3(*c*). This is frequently the case in caissons and pier foundations.

(*c*) The ultimate bearing capacity of a cohesionless soil increases approximately in direct proportion to the width of a loaded area.

(*d*) The ultimate bearing capacity of a cohesionless soil increases approximately as the square of the depth of the loaded area beneath adjacent ground surface.[2a]

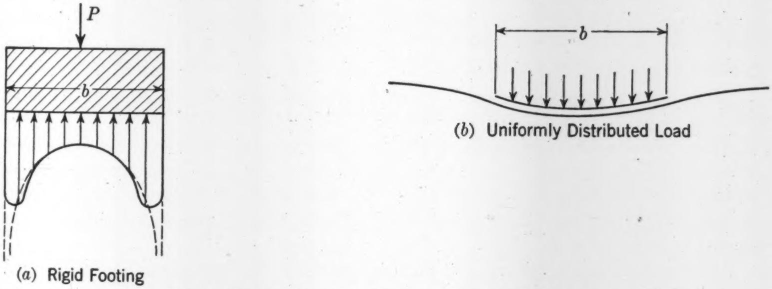
FIG. 3.—RIGID FOOTING ON THE SURFACE OF SAND

(*e*) Specifications for the allowable loads for sands, as generally given in building codes, do not take sufficiently into consideration the favorable influence of depth. Such "bearing values" are far too conservative for the case of footings founded at considerable depth, whereas, for narrow, interior, wall footings that are founded at the surface or at a shallow depth beneath immediately adjacent ground surface, the values are not sufficiently conservative.

(*f*) When fairly heavy loads are supported at shallow depths on narrow footings resting on loose sand, it is well to test the bearing capacity by loading a test area of similar width. However, for large areas on dense sand, or for areas which are to be founded at a considerable depth below ground surface on dense sand, even the heaviest loading which building codes permit is exceedingly conservative, so far as strength of the soil is concerned, and requires no verification by load tests.



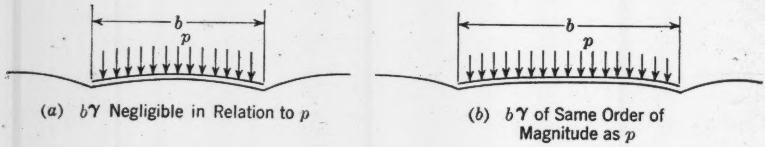
P
b
(a) Rigid Footing
b
(b) Uniformly Distributed Load

FIG. 4.—LOADS ON THE SURFACE OF ELASTIC MATERIAL

(*g*) From the theory of elasticity it follows that, for a perfectly elastic soil, the reactions on rigid areas and the settlements of uniformly loaded areas on the ground surface should be as shown in Fig. 4. The variations in pressure intensities and the settlement patterns thus obtained are just the opposite from those obtained in corresponding cases for sand, as shown in Figs. 3(*a*) and 5(*a*), respectively. Thus, in the case of sand, less harm would result from just guessing intelligently at the deflections or the distribution of soil reactions than from making elaborate computations on the basis of hypothetical theories which definitely do not apply. Furthermore, the fact that Hooke's law does not apply to cohesionless soils also invalidates the law of superposition. (Modifications of Boussinesq's formula,

---

[2a] See corrected statement in the closing discussion.



(*a*) $b\gamma$ Negligible in Relation to p (*b*) $b\gamma$ of Same Order of Magnitude as p

FIG. 5.—UNIFORMLY DISTRIBUTED LOAD ON THE SURFACE OF SAND

$$\sigma_z = \frac{3\,P}{2\,\pi}\,\frac{z^3}{R^5} \qquad (1a)$$

by introducing a "concentration factor," α, in the form,

$$\sigma_z = \frac{\alpha\,P}{2\,\pi}\,\frac{z^\alpha}{R^{\alpha+2}} \qquad (1b)$$

yield, when integrated over finite areas, essentially the same type of distribution as shown in Fig. 4. Therefore, this hypothetical solution, utilizing a concentration factor, is no improvement over the theory of elasticity. Both are equally unsuited for computing soil reactions and deflections on sand.)

(*h*) The settlement of a uniformly loaded area is a minimum in the center and a maximum along the edge. The deflection curve is as shown either in Fig. 5(*a*) or 5(*b*), depending on the relative magnitude of $b\,\gamma$ and p.

(*i*) The average settlement corresponding to a given unit load increases for small areas with increasing width of the footing, whereas for large areas it is practically independent of the width.

(*j*) The settlement for a given unit load decreases rapidly as the depth of the loaded area beneath adjacent ground surface increases.[2b]

(*k*) Sand layers provide an excellent medium for spreading load and for reducing differential settlements, due to the small strain which corresponds to ordinary loads and to the fact that the resistance of sand to deformation increases in proportion to the applied pressure. The presence of sand strata should be utilized as much as possible for this purpose.

(*l*) Conventional design of building foundations by means of individual column footings and wall footings, with or without piles, is in general entirely adequate for foundations on medium-grained and coarse-grained cohesionless soils, provided that borings to a depth at least equal to the width of the building have verified the fact that the sand is not underlain by a compressible stratum.

[2b] See modification in the closing discussion.

(*m*) When founding on very fine loose sand, settlements may become excessive. Very fine loose sands, rock flour, etc., may settle seriously at some later time, due to a lowering of the ground-water table, the driving of piles, or other disturbances caused by near-by construction operations.

Stress-Deformation Characteristics of Clays and Other Cohesive Soils.—Clays are very fine-grained soils having grain sizes which run well into the colloidal range. Such soils, when dried, become hard and appear like a soft rock. When remolded at consistencies between certain limiting water contents, clays exhibit the property of plasticity. With relatively little experience, clays can be identified in the field from an examination of these properties.

Since the plasticity, as well as the compressibility and permeability of a clay, is related to its content of colloidal, scale-like particles, the Atterberg liquid and plastic limit tests are useful for general classification purposes. Such classification tests, however, are far from adequate in quantitatively describing the pertinent properties of an undisturbed clay. With the same raw material, nature has made clays possessing widely different structural characteristics. These are dependent on many factors, as, for example, whether sedimentation took place in fresh or salt water and the amount of load under which consolidation proceeded.

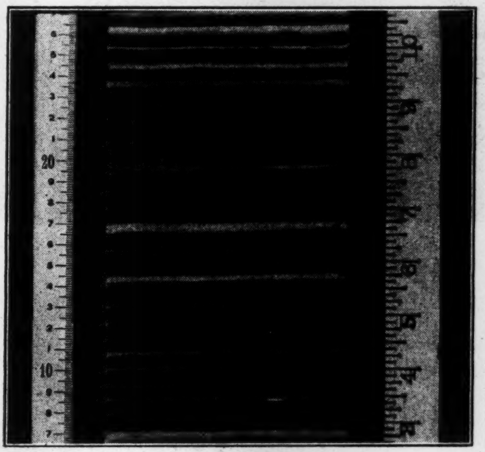


FIG. 6.—TYPICAL VARVED CLAY

Many undisturbed clays possess great strength in relation to their high void ratios.[3] A piece of such a clay can be broken like a soft solid, showing distinct rupture surfaces similar to those of brittle materials. However, if remolded without the addition of water, it becomes a plastic and very soft mass bearing no resemblance to the undisturbed soil.

Most undisturbed clays behave like a perfectly incompressible material immediately upon application of a load. If a load is maintained, however, water gradually will be squeezed out of those parts of the clay which are stressed, until the mineral skeleton is compressed to a volume at which it can carry the load. This process, which is called "consolidation," can be analyzed by means of the theory of consolidation[4] set forth by Karl Terzaghi, M. Am. Soc. C. E.

(a) and (b) Detail Views (c) Setup in a Loading Frame

FIG. 7.—CONSOLIDATION APPARATUS

Deformation of Clay Without Volume Change.—Stress-strain curves obtained from unconfined compression tests or surface-loading tests, on most undisturbed clays, are almost straight lines within the load range of working stresses. Hence, it should be possible to determine that part of the settlement of a structure which occurs during the application of load, and which is due to lateral deformation without volume change, by simply determining the modulus of elasticity and then applying appropriate formulas from the theory of elasticity. This approach has been tried by many investigators, and almost invariably it has been found that the actual settlements are only a fraction of the computed settlements. Some of this discrepancy is frequently due to the fact that the so-called "undisturbed samples" have suffered some disturbance during the sampling operations. In many cases this discrepancy is due to anisotropic characteristics of natural clay deposits.[5] Most clays are stratified, even though the stratification may not be visible. The most pronounced stratification is found in the so-called "varved" clays, in which thin layers of rock flour are closely laminated with clay layers of varying degrees of plasticity and frequently of varying colors. An excellent example of such a clay is shown in Fig. 6.

Whenever any type of stratification is present, the soft layers are confined laterally, to a certain extent, by the stronger sand and silt layers or partings. Hence, under the load of a building, that part of the settlement which is due to the lateral deformation of the underlying clay strata can develop only to a limited extent, as compared with the settlement which would take place if the clay were homogeneous and isotropic.

Consolidation of Clays.—There are many types of consolidation apparatus in use, all of which incorporate the principle, introduced by Professor Terzaghi, of compressing a thin cylindrical sample confined in a ring between two porous stones. The consolidation apparatus shown in detail in Fig. 7(*a*) and set up in a dead-weight loading frame in Fig. 7(*c*) is a simple and efficient example.[6] The test is performed by applying the load in increments. Each increment is allowed to remain on the sample a sufficient length of time for consolidation to take place, the extensometer being read at appropriate time intervals. The data of such a test are plotted in the form of a "pressure-void ratio curve" (Fig. 8) and a series of "consolidation curves" (Fig. 9).

Without presenting Professor Terzaghi's theory of consolidation of fine-grained soils in detail, the following points will be mentioned: The time required to reach a given degree of consolidation is directly proportional to the square of the height of a layer of clay, drained on both sides; it is inversely proportional to the coefficient of permeability; and it is directly proportional to the slope of the pressure-void ratio curve.

It is a simple matter to convert consolidation curves obtained in the laboratory to a curve showing the probable progress of settlement with time for a structure supported on the material from which the samples were obtained, provided the thickness and drainage characteristics of the loaded clay layers are known accurately. Unfortunately, this is seldom the case. When the soil conditions are complex, a tolerably accurate knowledge of the drainage characteristics can be obtained only by means of detailed underground explorations in which continuous samples are obtained. Even such an extensive study will provide information sufficient only to establish certain limits within which the actual conditions may lie. The range thus established may be quite wide.

Preconsolidation Load.—Correct interpretation of the results of consolidation test data is an important prerequisite for a comprehensive settlement analysis. The relation between pressure and void ratio, which is obtained from a consolidation test, may differ widely from the true relationship which a clay will follow in its undisturbed condition in the ground. It is necessary, therefore, to reconstruct this true relationship from the test data.

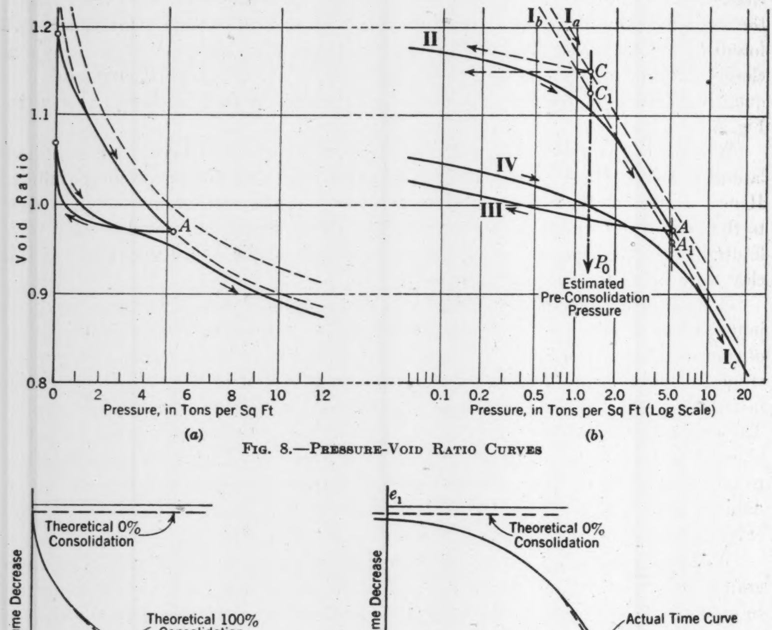

FIG. 8.—PRESSURE-VOID RATIO CURVES

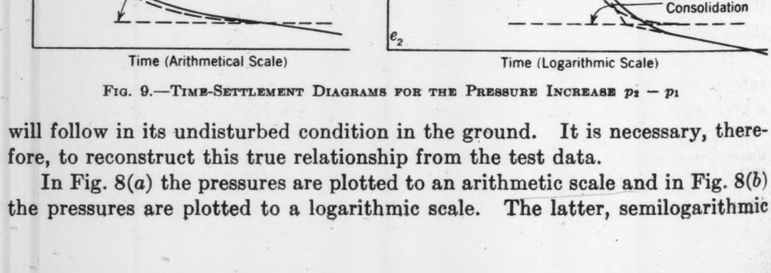

FIG. 9.—TIME-SETTLEMENT DIAGRAMS FOR THE PRESSURE INCREASE $p_2 - p_1$

In Fig. 8(a) the pressures are plotted to an arithmetic scale and in Fig. 8(b) the pressures are plotted to a logarithmic scale. The latter, semilogarithmic plot lends itself readily to an analysis of the loading history of a sample. The first part (II) of the compression curve is in reality a recompression curve which meets the virgin branch I_b and then continues along that branch as a straight line. At an arbitrary load, corresponding to point A, the load is reduced by a series of decrements to zero, and a rebound curve III is obtained. When load is applied again as before, the recompression curve IV is obtained. This latter curve meets the virgin compression curve I_c at a point corresponding to a higher pressure than that corresponding to point A. This diagram is typical of all very fine-grained soils. The magnitude of the drop in the position of a virgin branch after each rebound cycle depends chiefly on the structural characteristics of a soil.

The similarity in the shape of branch II, the relative positions of branches II and I_b with the shape of the recompression curve IV, and the relative positions of curves IV and I_c suggest that it should be possible to estimate the so-called preconsolidation pressure p_0, under which the soil was consolidated in the ground, from the data of a properly conducted consolidation test.

From a large number of tests on different types of soils, it has been found that the preconsolidation pressure for most clays can be determined with a satisfactory degree of accuracy by means of the empirical method shown in Fig. 10 and explained as follows: First, the position of the virgin compression line (I) is established by extending the straight-line part of the pressure-void ratio curve. Then, on the branch marked II, a tangent (t) and a horizontal line (h) are drawn at the point T which corresponds to the point having the smallest radius of curvature. The angle between (t) and (h) is then bisected, and the abscissa of the point of intersection C, of the bisector (c) with the virgin line I, determines the magnitude of the preconsolidation pressure (P_0).

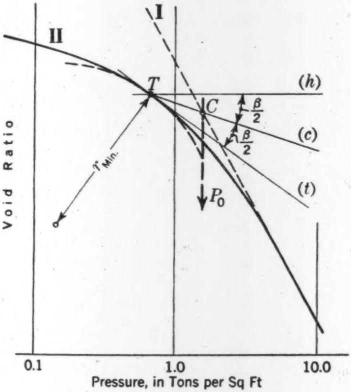

FIG. 10

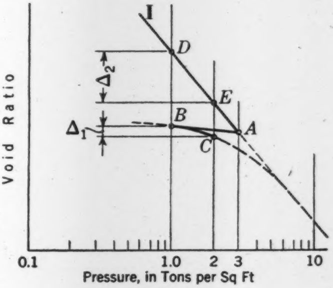

FIG. 11

The significance of this pressure can be demonstrated as follows: The slope of the virgin compression branch on a semilogarithmic plot is not noticeably affected by swelling and minor deformations of a sample. Hence, if a soil is completely consolidated under a pressure p_1 produced by an existing overburden, the compression due to any additional load Δp is determined easily by multiplying the thickness of the compressible stratum by the ratio of the change in void ratio $(e_1 - e_2)$ corresponding to a change in stress $(p_2 - p_1)$, divided by one plus the initial void ratio $(1 + e_1)$.

If the largest overburden to which a soil has been consolidated during its geologic history later has been partly removed, the compression due to the

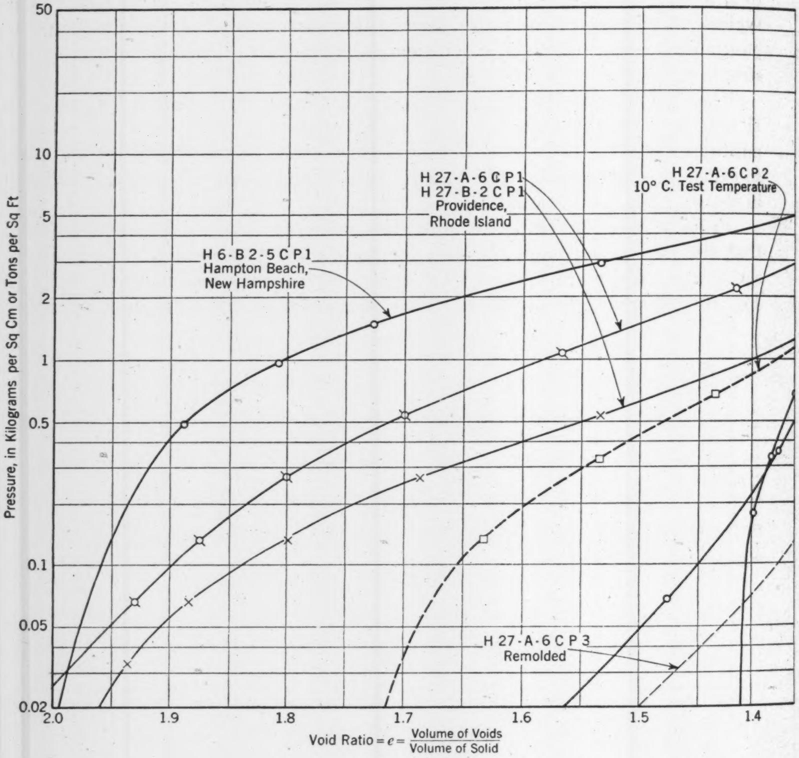

FIG. 12.—COMPRESSION

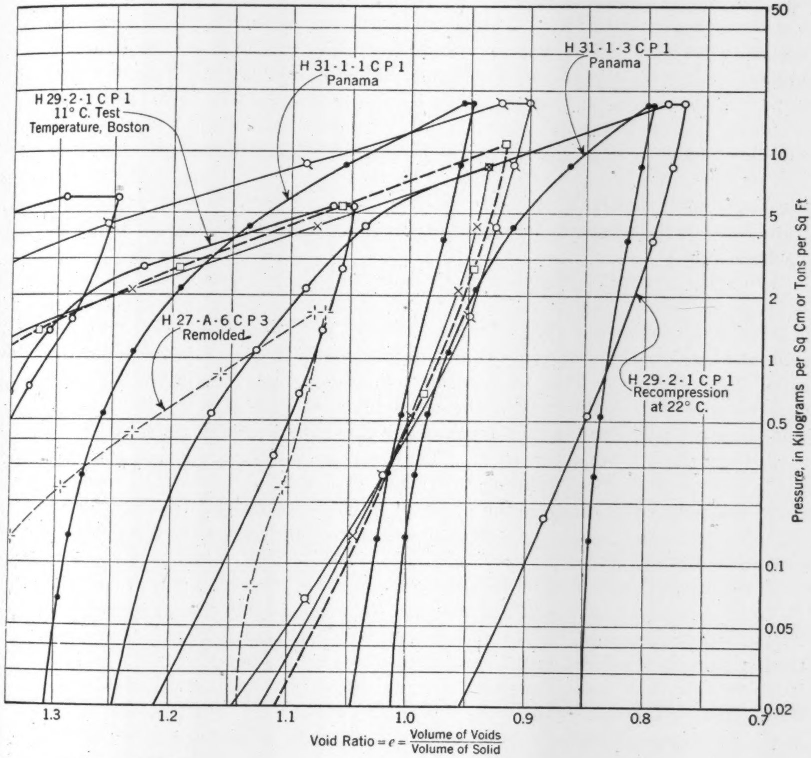
same pressure increase Δp will be much smaller, in spite of the fact that the virgin compression curve remains unchanged. For example (Fig. 11), if a clay layer has been compressed by an overburden pressure of 3 tons per sq ft and this pressure is later reduced by erosion to 1 ton per sq ft and then again increased to 2 tons per sq ft by the weight of a building, the consolidation due to the building load will correspond to a change, Δ_1, in void ratio. If, however, the clay has never been consolidated by a pressure in excess of the existing overburden pressure of 1 ton per sq ft, the additional stress due to the weight of the building would have produced a change, Δ_2, in void ratio, which is approximately five times as great as Δ_1. This example should suffice to illustrate the fundamental importance of a careful study of the preconsolidation pressure.

Many attempts have been made to arrive at a reasonable estimate of the compressibility of clays from tests which are more simple than the time-consuming consolidation test and which preferably could be performed on small, inexpensive samples. Utilizing a discovery by P. C. Rutledge,[7] Assoc. M. Am. Soc. C. E., that the pressure-void ratio curves for clays of the same general character follow a "pattern," it is possible in many cases to determine the compressibility approximately from the natural water content of the soil. This method will be explained by means of an example.



DIAGRAMS OF ORGANIC CLAYS

Example of a Settlement Analysis Based on Simple Soil Tests.—A power station had suffered serious settlement in spite of the "fact" that borings showed only sand to a depth of 35 ft and that piles had been driven to a depth of 25 ft to 30 ft. The writers were requested to make a preliminary investigation of the foundation conditions for a proposed extension of the plant. Four exploratory borings were made which revealed a stratum of slightly organic clay extending from approximately 39 ft to 51 ft beneath the ground surface. The clay stratum was underlain by a thick stratum of very compact sand. Almost continuous cores were obtained from the clay stratum by means of 4-ft sections of thin-walled steel tubing, 2 in. in diameter. The entire stratum was found to be fairly homogeneous, rather brittle in the undisturbed condition, and very soft and sticky when remolded. The natural water content ranged between 37% and 58%, the liquid limit between 37% and 65%, and the plastic limit between 20% and 27%. (Whenever the natural water content of a clay, which is consolidated by at least 40 ft of overburden, is almost as high as the liquid limit, it is an indication that the clay has the type of complicated structure which probably results from sedimentation in sea water. Numerous shells which were found in the clay were identified as being of marine origin.)

---

[7] "Compression Characteristics of Clays and Application to Settlement Analysis," by P. C. Rutledge, a thesis presented to the Graduate School of Eng., Harvard Univ., Cambridge, Mass., in June, 1939, in partial fulfilment of the requirements for the degree of Doctor of Science in Engineering.

From the general conditions at the site and the appearance of the clay stratum, it seemed likely that at no previous time did the clay layer carry a heavier overburden than that which existed at the time of inspection. It was evident also that this relatively thin stratum was fully consolidated under the existing overburden. The preconsolidation pressure was computed from the unit weights and thicknesses of the overlying materials at a depth of 45 ft, which corresponded to the mid-depth of the clay stratum, and was found to be approximately 1.5 tons per sq ft. The average water content of the clay stratum was 48%, corresponding to a void ratio of $e = 1.30$. The problem thus was reduced to finding the slope of a virgin compression curve for an organic clay which would compress under a load of 1.5 tons per sq ft to a void ratio of 1.30.

Pressure-void ratio curves for a number of different organic clays and silt-clays are assembled in Fig. 12 (rotated 90° to accommodate the page size). It happens that the curve for the soil used in test No. H27-B-2CPl passes practically through the point corresponding to $p = 1.5$ tons per sq ft and $e = 1.30$. If this were not the case, however, it would be a simple matter to draw a line through this point having the same slope as the other virgin compression curves in the immediate vicinity. Assuming that the average increase in stress due to the contemplated structure is 1.0 ton per sq ft, this increase in stress, according to Fig. 12, will reduce the void ratio of such a clay by about $\Delta e = 0.11$. Therefore, the total estimated compression of the clay stratum under the proposed load will be equal to $\frac{\Delta e}{1 + e}$ times the thickness of the layer—that is, $\frac{0.11}{2.3} \times 12 = 0.57$ ft.

Strength of Clay and Safety Against Rupture.—The question of safety against actual failure of the soil arises in connection with the question of the allowable pressure which a spread footing, pier, or caisson may exert on a soil. It cannot be overemphasized that a safe load, as far as rupture of the soil itself is concerned, may be anything but safe as far as the structure as a whole is concerned.

In a preceding section it was stated briefly that, with the exception of the case of a heavy load on narrow footings supported on or slightly below the ground surface, the possibility of stressing a cohesionless material to the point of rupture practically does not exist. In the case of clays, however, the situation is quite different.

The simplest approach to the problem of determining the ultimate bearing capacity of a clay is one which was originally suggested by Professor Terzaghi.[4] He assumed a wall footing of width 2 b resting directly on the ground surface, and assumed that the soil was divided into three square prisms as shown in Fig. 13(a). If the application of a load produces failure of the soil, the underlying prism will deform laterally. The resistance offered to this deformation will be dependent on the resistance to failure of the adjacent prisms.

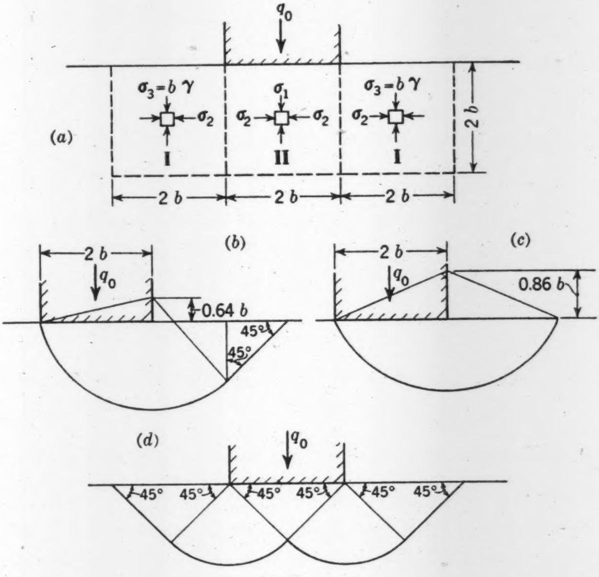


FIG. 13

If a load p per unit of area is applied quickly enough so that a clay will have no time to consolidate, the shear strength will be equal to a constant c; the Mohr rupture curve is represented by a straight line parallel to the pressure axis as shown in Fig. 14(a). Hence, if a clay is subjected to a quick loading, it may be considered to act as a purely cohesive material. This constant shear strength is frequently called "the cohesion of a clay." (The term "cohesion" has been used loosely in soil mechanics and has led to much confusion. In most cases it is used to designate the shear strength under zero normal pressure. This strength can vary between wide limits for the same clay.)

Referring to Fig. 14(*a*), circle I represents Mohr's circle of stress for the rupture condition of a small element in the center of prism I. The major principal stress, $\sigma_z = b\,\gamma + 2\,c$, which will produce failure, must be equal to the minor principal stress acting on a small element in the center of prism II. For the latter element, a major principal stress of $(b\,\gamma + 4\,c)$ will produce failure. Since the weight of the overlying soil produces a pressure $b\,\gamma$, it follows that the pressure q_o, which the footing must exert in order to produce failure according to this hypothesis, is equal to $4\,c$.

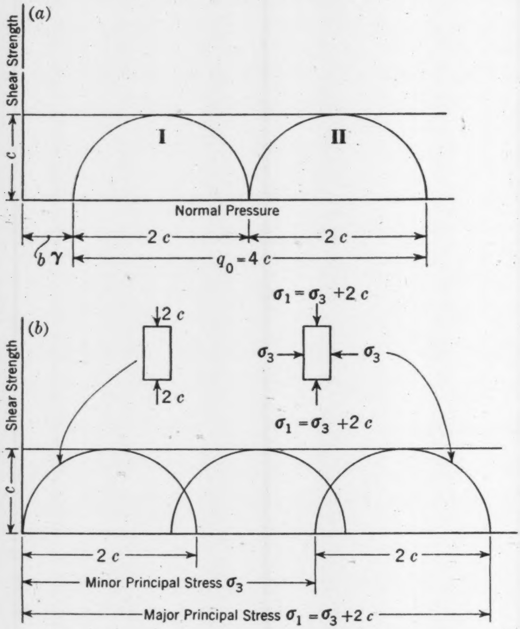

FIG. 14

Utilizing the principle of the Swedish method of cylindrical sliding surfaces, H. D. Krey[8] found that a combination of a circular sliding surface and a wedge, as shown in Fig. 13(*b*), will give the smallest resistance and a corresponding value of $q_o = 6\,c$. The senior writer found that, by the use of a circular sliding surface only, without a wedge, a value of $q_o = 5.5\,c$ is obtained. Guthlac Wilson,[9] M. Am. Soc. C. E., determined analytically that the exact position of the center of this circle is as shown in Fig. 13(*c*) and the exact value of $q_o = 5.4\,c$.

---

[8] "Erddruck, Erdwiderstand und Tragfähigkeit des Baugrundes," by H. D. Krey, 4th Ed., Berlin, Ernst, 1932.

[9] "The Calculation of the Bearing Capacity of Footings on Clay," by Guthlac Wilson, *Journal*, Institution of Civ. Engrs., November, 1941.

A satisfactory approach to the problem of bearing capacities of clay from an analytical point of view is by means of the theory of plasticity formulated by L. Prandtl.[10] He found that the shearing surfaces for an ideally plastic material are as shown in Fig. 13(*d*) and that, for a shear strength c, the failure unit load is $q_o = 5.14\ c$.

If clay were an ideally plastic material, the data from unconfined and triaxial compression tests on undisturbed samples would furnish a series of stress circles as shown in Fig. 14(*b*). In reality, the envelope obtained from a series of such tests is slightly inclined to the horizontal for homogeneous clays and is considerably inclined and curved for fissured clays and remolded, compacted clays. Unconfined compression tests on fissured clays have a tendency to produce rupture at a much smaller value than that indicated by the results of a series of triaxial tests. This is due to a premature disintegration of the specimens. If the confining pressure of a minor principal stress is acting, such as is the case in a surface-loading test or a triaxial compression test, this disintegration does not take place. For this reason, triaxial compression tests conducted at small lateral pressures are more satisfactory than unconfined compression tests for the determination of the c-value, which value one should use when translating results of compression tests on undisturbed clay specimens into ultimate bearing capacity for surface loading.

Compression tests on undisturbed soil cylinders are usually much less expensive than loading tests performed on sufficiently large areas. Therefore, the determination of the ultimate bearing capacity by means of cylinder compression tests is recommended. Since the allowable soil pressures commonly specified in building codes are conservative from the standpoint of safety against rupture of the clay, this indirect check of the ultimate bearing capacity is entirely satisfactory.

The problem becomes more difficult if the loaded areas are at a considerable depth below adjacent ground surface as, for example, in the case of caisson foundations. In such a case, the hydrostatic uplift of the soil may be added to the foregoing value of $5\ c$ and used as the ultimate bearing capacity. Actually, this value in such cases will be in excess of $(5\ c + \gamma\ h)$. There are no satisfactory theoretical solutions available, however.

EXAMPLES OF THE APPLICATION OF SOIL MECHANICS TO THE DESIGN OF BUILDING FOUNDATIONS

General.—Since it is difficult at present to set up general rules for the design of foundations on soft ground, the application of principles of soil mechanics can be demonstrated best by presenting the soil conditions in a large city, describing the types of foundations there used, and comparing the settlement records of five large buildings.

Foundation Conditions in Boston.—Large areas in Greater Boston are underlain by a thick stratum of soft glacial clay. A typical soil profile is shown in Fig. 15(*a*). The organic silt is so compressible that only very light buildings can be erected directly on the fill without suffering serious distress as a result of settlement. Therefore, it has been general practice to transfer building loads to the layer of hard or stiff clay below this stratum. Load transfer is accomplished either by means of spread footings, piles, or concrete piers with enlarged bottoms. In some areas a layer of sand instead of the hard clay is found overlying the soft clay, and in these areas piles usually have been used.

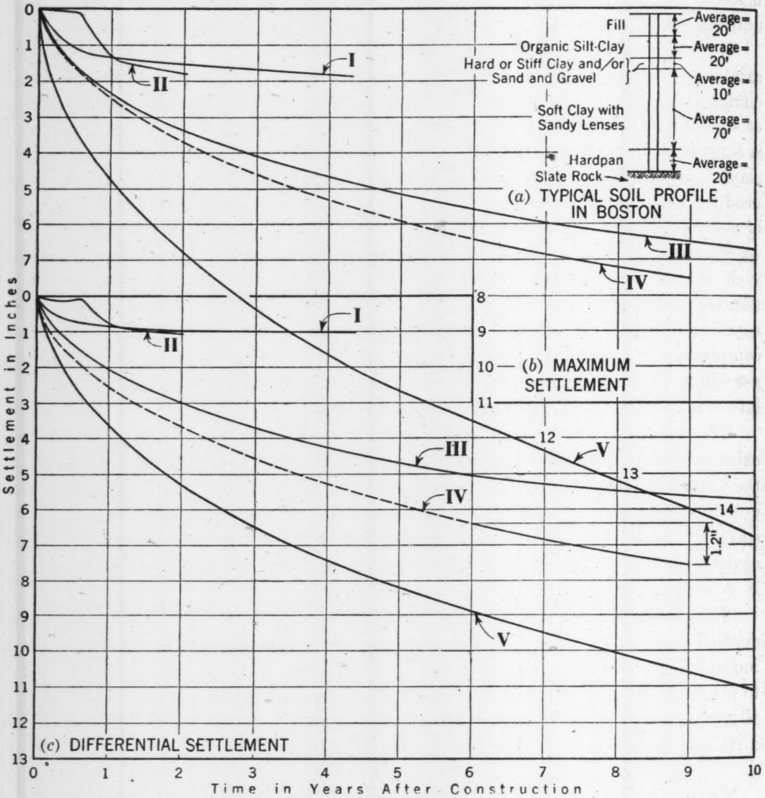

FIG. 15.—TIME-SETTLEMENT RECORDS, BOSTON, MASS.

Settlements of Buildings in Boston.—The weight of soil removed to provide basement space will compensate for the weight of an average building three or four stories in height. The presence of the thick, soft, clay substratum in Boston has had little effect on buildings of this type. Larger buildings, however, have suffered from progressive and differential settlements. Such settlements have been most pronounced in cases where a building, covering an extensive area, has produced different intensities of load on various sections of the building area. If no provision is made to equalize the net increase in pressure throughout the building area by increasing the depth of basement or sub-basement under the more heavily loaded sections, or to stiffen the structure, serious differential movements may occur.

Typical examples are shown by curves III, IV, and V in Figs. 15(*b*) and 15(*c*). The curves in Fig. 15(*b*) show the progress of movement of the point of maximum settlement in each of three different structures located within the confines of Greater Boston. The curves in Fig. 15(*c*) show the progress of differential settlement in these buildings.

The settlement represented by curves III occurred in a building supported on wood piles. These piles were driven into and, in some areas, through a stratum of sand underlain by soft clay. The thickness of soft clays varies from 55 ft to 85 ft throughout the area occupied by the building. In the most heavily loaded area, under a tower section, the average building load is equal to 1.2 tons per sq ft, and under a lighter wing of the building to 0.9 ton per sq ft. The average depth of soil removed under both sections was 10 ft. Hence, the net increase in pressure on the underlying soft clay varies between 0.6 ton per sq ft and 0.3 ton per sq ft. Furthermore, the thickness of the soft clay substratum is greatest under the more heavily loaded section. It is not surprising, therefore, that in the 10-yr period following construction the differential movement that developed between these two sections was equal to approximately 85% of the maximum settlement which occurred in the more heavily loaded section.

Curves IV correspond to another large building, for which settlement records were available only for a 3-yr period starting six years after construction. From an analysis of these data,[11] movements that had occurred prior to this period were estimated to be as shown by the dotted portions of these curves. The loads of this building are transmitted by spread footings to the top of a sand and gravel stratum, 12 ft thick. This stratum is underlain by 65 ft of soft clay. The soil conditions are comparatively uniform throughout the building area. The intensity of building load, however, varies from 2.1 tons per sq ft under a tower section to 1.2 tons per sq ft under an adjacent wing. The net increase in pressure, after deducting the weight of 15 ft of soil removed to provide basement space, is 1.4 tons per sq ft and 0.5 ton per sq ft, respectively. A contour map of the differential settlements which occurred in the 3-yr period starting six years after construction is shown in Fig. 16. (Contours represent points of equal settlement in reference to point A. The observation period equals three years, beginning six years after the erection of the building.) Curve IV in Fig. 15(*b*) shows the progress of settlement of point C in Fig. 16. Since a part of this building has not settled, this curve also represents the progress of differential movement. The rate at which this differential movement is progressing, approximately nine years after construction of the building, is 0.40 in. per yr.

---

[11] "Observations and Analysis of Building Settlements in Boston," by R. E. Fadum, a thesis submitted to the Faculty of the Graduate School of Eng., Harvard Univ., Cambridge, Mass., in May, 1941, in partial fulfilment of the requirements for the degree of Doctor of Science in Engineering (pp. 209–217).

A final example is shown by curves V in Figs. 15(*b*) and 15(*c*). The settlement represented by these curves occurred in a building supported by spread footings and concrete piers with enlarged bottoms bearing directly on a stratum of sand and gravel underlain by 90 ft of soft clay. The building loads in this case varied from 2.40 tons per sq ft under a tower section to 0.80 ton per sq ft under an adjacent wing. The net loads, after deducting the weight of soil removed from these areas, were 2.0 tons per sq ft and 0.7 ton per sq ft, respectively. The settlement of the tower section is shown by curve V in Fig. 15(*b*), and the differential settlement between the tower and this adjacent wing is shown by curve V in Fig. 15(*c*).

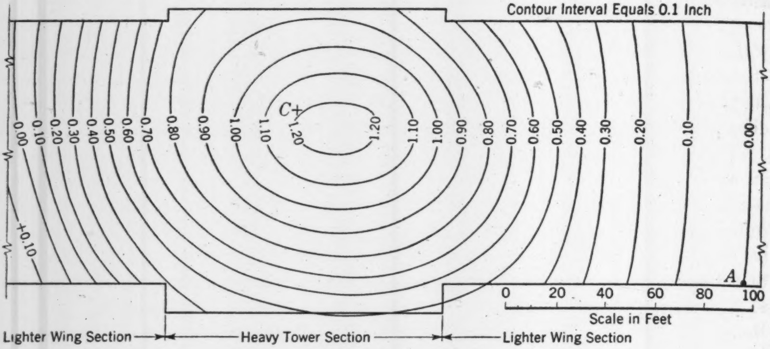

FIG. 16.—DIFFERENTIAL SETTLEMENT CONTOURS

Many other striking examples of serious settlements could be cited from other cities, and, were it not for a feeling of false shame that induces engineers and architects to withold permission for publication of the records of such settlements, it would be possible to add still more. Probably the largest settlements on record are those which have occurred in Mexico City, Mexico, where settlements are recorded in units of feet rather than inches. It is not surprising, therefore, that the principle of a "floating foundation" has been incorporated there without compromise in the design of a modern building.[12]

The experience gained from a study of observed settlements indicates forcefully that, for buildings covering large areas and producing considerable differences in loading between various sections, differential settlements can be reduced to a tolerable amount by excavating a quantity of soil approximately equal in weight to the load of the superimposed structure, so that there will be practically no net increase in stress in underlying soft clay strata. Even the fulfilment of this requirement will not eliminate settlements entirely, for the following reasons:

(*a*) The removal of a large mass of soil will produce an elastic deformation of the underlying soil resulting in a slight upheaval of the bottom of the excavated pit. Upon replacing the weight of soil removed by the weight of the building, corresponding settlement will take place. Because of the confining effect of the edges and the corners of an excavated pit, this upheaval and subsequent settlement theoretically should be largest in the center of the area, approximately one half of this value along the edges and one quarter at the corners. The actual magnitude of the upheaval is dependent chiefly on the lateral reinforcement of the soft soil by sand layers and lenses. Although it is known that this lateral deformation can assume large proportions for more homogeneous deposits of very soft clay, such as those which exist in Mexico City, no serious movements have ever been observed in Boston. This upheaval was measured, as will be described subsequently, during construction of a large building in Boston.

---

[12] "The Floating Foundation of the New Building for the National Lottery of Mexico," by Jose A. Cuevas, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., June, 1936.

(*b*) Since building loads are usually transferred on to a bearing stratum by means of individual column footings, wall footings, caissons, or pile clusters which cover only part of an entire building area, loads concentrated on this stratum will cause a slight deformation and consolidation of the soil immediately below the footings. Again the amount of settlement due to this cause will be reduced along the edges and particularly at the corners of a building area, due to the increased lateral confinement of the soil at these places.

(*c*) If the bearing stratum is very thin, there will be a net increase in stress in limited volumes of the softer soil underlying the bearing stratum. The soil will adjust itself to these increased stresses chiefly by consolidation and to a small degree also by lateral deformation.

The experience of recent years confirms the requirements for the design of building foundations which one of the writers expressed[3] in 1932 in the following conclusion:

> "* * * the whole problem of building foundations on clay boils down to these two simple principles: first, do not disturb the natural structure of the clay; if you do, no human being is able to restore its original strength; second, decide on a certain rate of settlement which you do not wish to exceed, and determine that pressure which will cause this rate of settlement; the difference between the building load and the above pressure is the weight of soil which must be removed before erecting the building * * *."

Special attention should be given to the magnitude of the differential settlements, which are dependent on the design of the building, the soil conditions, and inequalities in the preconsolidation load. In addition, it should be noted that the allowable magnitude, rate, and distribution of settlement depend to a large extent on the type of building. It is obvious that a masonry facing consisting of 4-ft by 6-ft limestone blocks, with very thin joints, is many times more sensitive to differential settlements than, for example, a brick building.

The Liberty Mutual Insurance Company Building in Boston.—An example of the application of soil mechanics to the design of the foundations for a typical office building is furnished by the Liberty Mutual Insurance Company Building which was built in 1936–1937. This building has a plan area 270 ft by 116 ft, and consists of a heavy tower section and two lighter wings. It is faced with large, thin, limestone blocks which are very sensitive to differential movements. The basement was so designed that the weight of the soil excavated was slightly less than the building load on all sections of the plan area occupied by the building.

The building load is transferred to the basement by a great number of columns, which in turn are transferred by concrete piers on to the surface of a hard clay stratum at a depth of about 40 ft below ground surface. The bottoms of the piers are increased in area by means of bells, the diameters of which are governed by the column loads as well as by the thickness of the underlying hard clay stratum. The allowable load on the hard clay was determined from compression tests on undisturbed samples. The hard clay, which averages 10 ft in thickness, is underlain by 60 ft of soft clay.

FIG. 17.—FOUNDATION PLAN, LIBERTY

To reduce the differential settlement of the exterior foundation walls to a minimum, they were designed as heavily reinforced girders. To reduce the differential settlement between the exterior foundation walls and the interior footings, these walls are supported by cantilever beams which transfer the wall loads to piers carrying interior columns. This arrangement increases the absolute settlement of the circumferential wall, but in so doing it decreases the differential movement in reference to the interior of the building. Only at those points where it was not possible to arrange a cantilever system were piers placed directly beneath the walls.

Mutual Insurance Company Building

The foundation plan for this building is shown in Fig. 17. The small dark squares represent interior column locations, the shaded areas represent mats, and the circles represent the diameters of pier bells bearing on the stratum of hard clay. The contours represent points of equal settlement in reference to a permanent bench mark for a period of 4.3 years.

The building load varies from 1.3 tons per sq ft under the central tower section to 0.8 ton per sq ft under the adjacent wings. To equalize the net increase of pressure throughout the building area, a sub-basement was installed under the tower section. Thus, the net increase in pressure was made equal to 0.2 ton per sq ft in all areas.

The small numbered circles in Fig. 17 designate the locations of permanent settlement observation points which were established during the construction of the substructure. The elevations of these points were determined periodically by means of precision water-level surveys in reference to a permanent bench mark that was installed in one corner of the basement. The bench mark was installed by driving a pipe through an exterior permanent casing into hardpan directly overlying bedrock to a total depth of 120 ft below the original ground surface. The experience gained from conducting level surveys with this water-level precision instrument[13] has shown that with reasonable care a line of levels can be made around a closed loop containing about twenty observation points with an average error of closure of 0.012 in. Such a level survey can be made without difficulty in basements that are fully utilized for storage purposes.

As stated, the contours in Fig. 17 show the lines of equal settlement. These settlements occurred in a period of 4.3 years following installation of the observation points. The time-settlement curve for the point marked A, at which the maximum settlement has been observed, is shown by curve I in Fig. 15(*b*). This curve shows a rate of increase, 4.3 years after construction, of only 0.12 in. per yr, as compared with a rate of 0.40 in. per yr observed some nine years after construction in a building, previously mentioned, of similar weight and size. The maximum differential settlement at this time is slightly in excess of 1.0 in., and the rate of increase as shown by curve I in Fig. 15(*c*) is negligible.

The New England Mutual Life Insurance Company Building.—A more difficult foundation problem than that which was encountered in the case just described presented itself in connection with the design of the foundations for the New England Mutual Life Insurance Company Building. The subsoil conditions are very similar in both cases. However, the following complications had to be considered in the latter case: Two sections of the building area were pre-loaded by two fairly heavy buildings that were removed just prior to the construction of the new building. An equal area between these buildings, where the heaviest section of the proposed building was to be located, had never before been loaded. The building was to cover an area of 340 ft by 200 ft and was to consist of a heavy ten-story section occupying a "T-shaped" area, and one one-story, two two-story, and two four-story sections. The one-story and four-story sections, at some future time, might be built up to the full height of the heavy ten-story section. The foundations had to be designed to provide not only for the first stage of construction, but also for all enlargements contemplated for the future.

Extensive underground explorations were undertaken. Nine exploratory borings were made from which almost continuous thin-walled tube samples were obtained from the hard and soft clay strata. Two large-diameter borings were then made for the purpose of obtaining undisturbed samples for laboratory investigations of the compressibility characteristics of the material below the elevation at which the building was to be founded.

---

[13] The type of instrument used in these surveys is described in "Practical Application of Soil Mechanics: Settlement of Structures in Europe and Methods of Observations," by Karl Terzaghi, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), pp. 1432–1448, particularly pp. 1433–1436.

Settlement investigations for various preliminary designs of the building indicated that, with the aforementioned complications, serious differential settlements could be avoided only by using the principle of a floating foundation, thereby excavating as much soil as the building, including the anticipated future enlargements, would weigh. This estimated weight was 130,000 tons as compared with 40,000 tons for the Liberty Mutual Building.

The weight of soil to be removed, necessary to counterbalance the load of the building in all sections of the area occupied by the building, required excavating to an average depth of approximately 35 ft. For this reason it became apparent that a sub-basement, which was not originally contemplated by the owners, would be necessary. The suggestion of such a sub-basement, however, was welcomed as an area for garaging automobiles, since the parking difficulties in this section of the city are particularly acute.

The only other feasible solution of this foundation problem would have been to transfer the entire building load by means of piles or piers on to the hardpan underlying the soft clay stratum at a depth of at least 125 ft beneath the original ground surface. A preliminary comparison of the cost of this type of foundation with a floating type of foundation showed that the transfer of the load to the hardpan would be considerably more expensive.

The design of the foundation was influenced vitally by the fact that the functional requirements called for clear working spaces, free of columns. This type of load distribution lent itself to the design shown in Fig. 18(*a*). The circumferential lines and the lines EF, GH, IJ, KL, MN, and OP represent the main walls of the building which carry the major part of the building load. These walls are extended through the sub-basement and the basement and are heavily reinforced to provide sufficient stiffness to reduce differential settlements that might result from irregularities in thickness and consistency of the hard clay stratum. It was determined, from load tests and unconfined and triaxial compression tests, that the allowable load on the hard clay should not exceed 4 tons per sq ft. The widths of the wall footings as shown by the dotted lines in the foundation plan, Fig. 18(*a*) are such that this unit load is not exceeded. The bearing pressure under the circumferential walls was increased in relation to the unit load for the interior wall footings to reduce the differential settlements between the outside and the inside walls. An additional increase in the design unit load on the hard clay was provided at the corners of the building by decreasing the footing widths at these locations.

Typical cross sections, showing the sections of the walls, wall footings, and basement slabs, are given in Figs. 18(*b*), 18(*c*), and 18(*d*).

The uplift produced by a head of 22 ft of water controlled the design of the sub-basement slab in most instances. Exceptions to this are found in those areas where columns and heavy equipment, such as boilers, rest directly on the slab. Thicker slabs were necessary to provide for these loads. The column loads are not carried directly down to the hard clay, but are transferred

(d) SECTION 1-1

Fig. 18.—New England Mutual Life Insurance Company Building

to the main walls for the purpose of eliminating serious differential movements between the individual columns and the main walls. The objection might be raised that a more economical transfer of load might have been arranged by the use of individual girders beneath the sub-basement floor. Unfortunately, the depth of girders required would have been such that the girders would have borne on the hard clay and thereby defeated the purpose of the load transfer. With the exception of the small rectangular area bounded by MNOP in Fig. 18(*a*), all of the sub-basement floors are supported on the main walls and are separated from the hard clay by at least 3 ft of the highly compressible, organic silt-clay. It was specified that, if it were discovered, during the progress of construction, that the hard clay in some areas approached the bottom of the sub-basement slabs, it would be necessary to excavate to a sufficient depth and replace the hard clay by soft organic silt-clay.

The unsymmetrical footings of the circumferential walls, shown in Fig. 19(*b*), evolved from adapting considerations of soil mechanics and requirements for simplicity and economy of construction to the conventional type of footing shown in Fig. 19(*a*). By cutting off the outside of the footing and extending the inside, and by filling the space between the footing and slab, the following advantages were gained:

(1) Increased settlement of the circumferential walls, and thereby a decrease in differential settlement;
(2) Material reduction in the span of the sub-basement slabs; and
(3) A simple and economical method of construction.

FIG. 19.—UNSYMMETRICAL FOOTINGS OF THE CIRCUMFERENTIAL WALLS

The general excavation was carried first to a depth of about 20 ft, to the top of the organic silt-clay, and from there vertical H-section piles, as shown in Fig. 19(*b*), were driven. As the excavating proceeded, horizontal and inclined H-section braces were installed. These bore against sections of the slab that had been installed prior to excavating the final berm. The horizontal braces were later concreted into the slab, and the inclined braces were cut off.

Overburden (wet) = 2.24 tons per sq ft.

FIG. 20.—FOUNDATION MOVEMENTS, NEW ENGLAND MUTUAL LIFE INSURANCE COMPANY BUILDING

The vertical piles and horizontal wooden sheeting remained in place and were used as the outside form work. The development of this ingenious solution is essentially due to L. S. Homer, M. Am. Soc. C. E., superintendent for the Turner Construction Company.

Observations of Movements.—It was stated that, if a foundation is designed in such a manner as to produce a zero net increase in stress in underlying compressible soil after excavating and building operations are completed, the major part of the subsequent settlement of a structure is due to the elastic deformation and the consolidation of the soil immediately below the footings. Were it possible to distribute the building load uniformly over the building area, and were it possible to excavate and apply the building load simultane-

ously, no settlement would result. However, it is impracticable to design and construct a building in such a manner that these requirements are fulfilled, and it is necessary, therefore, to investigate the consequences that might result if these two conditions are not fulfilled.

For this purpose an effort was made to obtain a record of the movement of the bearing stratum during and subsequent to all construction operations. To obtain this record, it was necessary to measure the rise in elevation of this stratum, resulting from the removal of an average of 35 ft of overburden, and then to determine the downward movement which took place when the weight of the foundations and superstructure was added.

Prior to excavating, underground reference points were established at eight locations in one quadrant of the building area, as shown in Figs. 20 and 21. These reference points consisted of 2-in. tubes, each 6 ft in length, which were driven into the hard clay. This was accomplished at each location by advancing the casing to the top of the hard clay. After the casing had been cleaned out, a steel tube was lowered and driven 6 ft. The elevation of the top of the tube was then established. For the purpose of marking the location of each tube, colored wooden sticks, which were weighted to prevent flotation, were lowered as the casing was withdrawn.

The movements recorded for each point are given in the table in Fig. 20. The maximum upward movement observed when the eight points were first uncovered was 2.9 in., at point 5 in the center of the area, and the minimum was 1.3 in., at point 1, which is located on the shorter axis near the periphery of the building area. The second set of observations, which was made on six of the points one week after they were first uncovered, and just prior to installing the sub-basement slab, showed that in this period they had continued to rise so that the ultimate total rise for each point was approximately the same.

Settlements resulting from the placing of wall footings 10 ft thick and adjacent sub-basement slabs were determined at the location marked "B" in Fig. 20 by observing the movement of the top of a 1½-in. steel rod which had been driven 3 ft into the hard clay. This rod, which projected up through a piece of pipe encased in the concrete, settled approximately 0.5 in. during the placing of the concrete. Subsequent observations which were made at periodic intervals in reference to a permanent bench mark (of the type installed in the Liberty Mutual Insurance Company Building) showed that this point moved downward as follows:

Time of observation	Approximate load (tons per sq ft)	Total downward movement (inches)
As concrete was placed	0.75	0.5
After six days	0.75	0.75
After one month	1.00	1.00
After two and one-half months	1.25	1.00
After three months	1.75	1.25

—a total of 1¼ in. during the three-month period following the installation of the concrete slab and footings at this location. At the end of this three-month period, during the installation of the basement walls, permanent observation points were established at seventy-three locations throughout the sub-basement area. The elevations of these points were observed periodically in reference to the permanent bench mark by means of precision water-level surveys. Point 9 (see Fig. 18(*a*)) was located within 10 ft of the locations of underground observation points 2 and B, thus affording a means of continuing observations of the movement of the bearing stratum at this location.

At point A, Fig. 20, a 4-in. boring had been made in April, 1938. When the overburden was removed in October, 1939, this hole was found to have been reduced to 2.5 in.

The top of a pile driven at point C (see Fig. 21) was observed in October, 1939, to have moved inward ¾ in. and to have been raised ½ in. In December, 1939, after the exterior footings and walls had been poured, this pile had moved downward ¾ in.

After the excavation and shoring were completed, the street curbs moved in about 1¼ in. and down about 1¼ in. No horizontal or vertical movement was observed in adjacent buildings.

A continuous record of the movements that occurred during the construction period, following the demolition of buildings which formerly occupied the site, together with diagrams which show the change in net unit load at this location, are shown in Fig. 22. The shaded diagram represents the net unit load on the bearing stratum at the location of the intersection of two interior cross-wall footings (see Fig. 18(*a*)) where points 2, B, and 9 are located. The net unit load at point B is 1.41 tons per sq ft. The dotted diagram shows the average net unit load (= − 0.39 ton per sq ft) on the area marked "A" in Fig. 18(*a*). This area includes one half of the unloaded area adjacent to these wall footings. The ordinates of both diagrams show the net change in unit load resulting from all construction operations—that is, the algebraic sum of the unit load

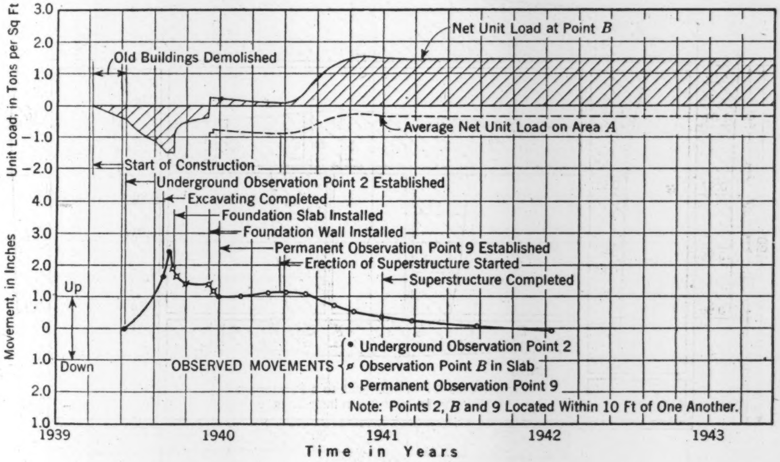

FIG. 22.—TIME-LOAD DIAGRAMS AND OBSERVED MOVEMENTS

removed by the demolition of old buildings, the unit load removed by excavating an average of 35 ft of soil, the temporary unit load added by the lowering of the ground-water table during construction, and the unit load of the foundations and superstructure of the new building.

The shaded diagram shows an ultimate local increase in pressure immediately below the wall footings. The dotted diagram, which represents the average change in unit load for a typical section of the building area, including unloaded parts, shows an ultimate net decrease at the conclusion of all construction operations. Therefore, the subsoil is subject to an increase in pressure only to a limited depth below the footings, and for this reason only a comparatively small volume of soil will be compressed.

The loading diagrams assist in an interpretation of the curve showing the foundation movements. This latter curve shows that during the excavating period the bearing stratum rose 2.40 in. After the foundations had been installed, it settled back 1.40 in. In the six-month period that followed, during which time hydrostatic pressure was increasing under the slab with very little building weight being added, a slight rise in elevation took place. Then, as the building load increased rather rapidly during the erection of the superstructure, the stratum began to settle. As of January 15, 1942, which was approximately one year after the superstructure was substantially completed, the net movement was 0.06 in. downward. It will be noted that, of the total downward movement (2.46 in.), 1.40 in. occurred during construction of the foundations prior to erection of the superstructure.

Note:
Settlements Are in Reference to a Permanent Benchmark and Are in Inch Units.

FIG. 23.—SETTLEMENT PROFILES, NEW ENGLAND MUTUAL LIFE INSURANCE COMPANY BUILDING

The movements that have occurred at other points throughout the building area, as determined from periodic precision water-level surveys of the permanent observation points, are shown by the settlement profiles in Fig. 23. The settlements that are represented by these profiles have occurred in the 2-yr period following the installation of the foundation walls. The settlements thus represented include the movements which took place during erection of the superstructure. These profiles show little differential movement.

The progress of settlement of the point at which the maximum settlement has occurred is shown by curve II in Fig. 15(*b*). The maximum differential settlement determined from the seventy-three points under observation is shown by curve II in Fig. 15(*c*). The trend of these curves is sufficiently well established to indicate that future settlements will be of a small order of magnitude.

CONCLUSIONS

(1) The analysis of observed settlements of buildings in Boston shows clearly that settlements can be reduced to a tolerable magnitude by removing a quantity of soil which, in weight, is approximately equal to that of the superimposed structure.

(2) This method of "floating" a building is particularly adaptable to locations where a suitable bearing stratum is located from 20 to 40 ft below the ground surface and where soil and ground-water conditions permit the necessary excavating.

(3) A structure that is underlain by soft soil, and which obtains support from such soil, will undergo some settlement even though the weight of the structure does not exceed the weight of soil removed. The removal of a mass of soil will cause an upheaval of the bottom of an excavated pit, due in part to a deformation and in part to a swelling of the underlying soil. Upon reestablishing the original stress conditions, a settlement at least equal to the magnitude of the upheaval will take place.

(4) The settlements due to deformation and recompression following swelling take place essentially during the construction period. Progressive settlements will occur subsequent to this period for many years at a decreasing rate if the weight of the structure is greater than the weight removed from the building area prior to its construction.

(5) Differential settlements are best controlled by designing the foundation and the superstructure as an integral unit, with special attention to stiffness. Where this is not acceptable, design for stiffness must be confined to the foundation, which increases the cost and decreases its effectiveness.

(6) Differential settlements can be controlled to some extent by increasing the unit loading on those areas where the smallest progressive settlements are anticipated and decreasing the unit loading where the largest progressive settlements are anticipated.

ACKNOWLEDGMENTS

The writers wish to acknowledge gratefully the cooperation of Chester Lindsay Churchill, architect for the Liberty Mutual Insurance Company

Building; C. N. Godfrey of the architectural firm of Cram and Ferguson, which designed the New England Mutual Life Insurance Company Building; the Turner Construction Company, and in particular L. S. Homer, superintendent of construction for both the Liberty Mutual and the New England Mutual Insurance Company buildings; H. A. Mohr, M. Am. Soc. C. E., of the Raymond Concrete Pile Company; and the City of Boston Building Department. Messrs. P. C. Rutledge, F. M. Baron, Assoc. M. Am. Soc. C. E., and E. M. Fucik and K. S. Lane, Juniors, Am. Soc. C. E., former members of the staff of the Graduate School of Engineering, Harvard University, Cambridge, Mass., assisted the writers in the design of the foundations of these buildings. J. A. Delaney, a present member of the staff, assisted in conducting level surveys. M. J. Hvorslev, Assoc. M. Am. Soc. C. E., supplied copy for Fig. 6; and reproduction of the information in Figs. 20 and 21 was made possible through the courtesy of the Turner Construction Company.

APPENDIX

NOTATION

The following letter symbols, used in this paper, conform essentially to "Soil Mechanics Nomenclature"[14] presented in 1941 by the Committee of the Soil Mechanics and Foundations Division on Glossary of Terms and Definitions and on Soil Classification:

A = area covered by a footing;
b = width of a footing;
c = a constant shear strength;
e = void ratio;
h = depth of a footing;
P = concentrated, or equivalent concentrated, load on a footing;
p = average unit load on a footing;
q_o = average unit pressure exerted by a footing;
$R = \sqrt{r^2 + z^2}$;
r = radius or radial distances from an axis;
z = distance parallel to the z-axis (depths), measured from the base of the footing;
α = a concentration factor (Eq. 1*b*);
β = an angle in Fig. 10;
γ = weight of soil per unit volume;
Δ = increment of increase; thus: Δp = any additional unit pressure; Δe = change in void ratio, etc ;
δ = unit strain; and
σ = principal stress.

DISCUSSION

Jacob Feld,[15] M. Am. Soc. C. E.—The use and the limitations of soil tests and soil theories that should be considered in building foundation design are summarized in this paper. Definite rules are set forth for cohesionless soils, and the general advice is given that the "floating method" be used in cohesive soils.

The thirteen conclusions and recommendations listed for cohesionless soils (see heading: "Introduction—Stress-Deformation Characteristics of Cohesionless Soils") are open to question since, in some instances, they do not agree with either experiment or experiences. For example:

(*a*) There is no justification for the assumption that the intensity of pressure at the edge of a rigid area is zero. The experimental works of W. S. Housel,[16] M. Am. Soc. C. E., of R. B. Fehr and C. R. Thomas,[17] and of Frederick J. Converse,[18] Assoc. M. Am. Soc. C. E., definitely show the existence of some pressure along the edges of footings laid in sand.

(*b*) The uniformity of base pressure in pier foundations is the result of the rigidity of a deep footing rather than of the depth of the footing. Similar uniformity of base pressure should be expected under a gravity type of abutment built in a shallow excavation.

(*c*) A rewording of this rule might clarify its meaning, to the effect that the unit bearing is independent of the width of the loaded area. However, this is not consistent with conclusion (*i*). The effect of footing shape should be considered, as well as the corresponding effect of edge resistance in sustaining loads.

(*d*) This rule is not substantiated by tests of bearing values on deep caissons. The more likely rule should read:

"The increase in ultimate bearing capacity of a cohesionless soil with depth is approximately as the square of the depth of the loaded area."

(*e*) and (*f*) The author suggests correctly that, taking depth into account, different allowable bearing values should be assumed for interior and exterior wall footings.

(*g*) The elimination of the Boussinesq formula as a tool to indicate the range of expected values is not wise until a more accurate method is devised. Although the Boussinesq formula is based on the assumption of isotropic elastic materials (which assumption does not include soils at failure), it should be emphasized that the theory of elasticity of materials is similarly limited. Since, under small loadings, the strains in soils are substantially homogeneous and the lack of tensile strength does not come into play until the tensile components of internal shear strains exceed the initial compression, there is a range of loading for which the Boussinesq formula, in the original or modified form, does serve a useful purpose.

In the list of recommendations for noncohesive soils, at least a warning of the effect of unwatering on settlements also should be included.

The statement that the action of foundations in clays can be properly predicted only if the loads are placed in excavations deep enough to "float" the building, is wise. Mention might be made of the practice in clay localities (Texas, Connecticut, etc.) of not removing the last foot or so of the excavation until just before placing the concrete so as to reduce the settlement from recompression of the clay swelling at subgrade.

Much can be learned of foundation design by the analysis of corrective measures for buildings showing differential settlements. The writer described a few cases in a paper in 1930.[19] A list of references on the subject of bearing capacity published before 1913, in readily available literature as determined for the design of structures now in use, is as follows:

LEONARD ZEEVAERT,[20] JUN. AM. SOC. C. E.—The material contained in the paper is of great value and very encouraging for it shows the ready application of soil mechanics in the design of building foundations. The writer has had the opportunity to design the foundations for three buildings constructed in Mexico City, Mexico, in which principles similar to the ones stated in the paper have been used.

In each of these buildings the basement was excavated to variable depths to give a more uniform and favorable distribution of loading and thus to decrease the dishing effect. Early indications show greatly decreased dishing as compared to similar adjacent buildings and to other buildings in the city which, according to usual practice, have equal depth of excavation throughout the foundation area. Decreased average settlements are obtained because of the more uniform stresses within the clay strata. The writer found that the idea of excavating to variable depths in order to create more uniform stresses in the compressible strata, and therefore to reduce differential settlements, helps considerably and is readily applicable to very compressible soils, such as Mexico City clays. He has called this type of foundation a "compensated foundation."

To compute the load distribution on the foundation slab when a rigid foundation is to be used in connection with underlying clay, "the edge load problem" was devised. The compensated excavation and an edge load applied along the boundary of the foundation are the means used to obtain an essentially uniform stress in the clay stratum below the structure. The load thus applied at the surface to hold these uniform stresses within the clay stratum is the load used to compute the foundation structure of the building in question.

---

[20] Prof., Soil Mechanics, School of Civ. Eng., Univ. of Mexico; Cons. Engr., Mexico City, Mexico.

One example of the aforementioned items is the Wong Office Building (165 by 56 ft and 105 ft high) under which there is a stiff fill underlain by a very soft clay stratum extending about 90 ft to the underlying sand stratum. The building is of concrete with an average net load of 0.9 ton per sq ft. In this case, the ratio of the load of the building to the weight of the soil excavated was about 9 to 5. In the analysis it was recognized that adjacent buildings transmitted considerable stress to the clay beneath the Wong Building and these stresses were taken into account in the settlement analysis.

FIG. 24.

The solution of the edge load problem is explained briefly by reference to Figs. 24(*a*) to 24(*e*). Fig. 24(*a*) shows the stress distribution under the foundation and strata due to a flexible foundation on clay, and Fig. 24(*b*) shows the same for a rigid foundation. Therefore, in a foundation that may be considered rigid, the stress distribution in the clay stratum and the load distribution on the surface must be approached as demonstrated in Fig. 24(*b*). By "compensating" the excavation, the first step to this approach is obtained. Fig. 24(*c*) shows the improved distribution of stress in the clay strata. However, there will be a drop in the stress distribution within the clay strata (Fig. 24(*c*)) at the ends corresponding to the boundary of the excavation. Therefore, unless the foundation of the building is sufficiently rigid, dishing the foundation structure is possible. By applying edge loads as shown in Fig. 24(*d*), a fairly uniform stress to the very edge of the foundation and, at the same time, a load distribution on the surface that approaches the distribution for a rigid foundation (Fig. 24(*e*)) may be obtained. This load can be supplied by designing the foundation sufficiently rigid.

This building indicated an average settlement of 1.2 in. in nine months after the excavation load was reached, and, three months later, a total settlement of 1.6 in. after application of practically all load. The differential settlements were of the order of 0.08 in. (maximum) at points of about 50 ft apart. The settlement analysis indicated 2 in. at the end of the construction period and about 16 in. per decade after application of the load. Early in the construction period the settlements were 0.8 in. greater at one end, because this end during the construction period was more heavily loaded than the remainder of the building, but the tilting of the foundation did not exceed 0.8 in. at the completion of the loading period. Differential settlements remained under 0.08 in., and no dishing effect has been noticed. The excavation depths were not appreciably greater than those commonly used in Mexico City. A regular concrete foundation with beams and 10-in. thick slabs was used, and no cracks have developed. This is of particular significance as, in Mexico City, most buildings with fewer stories have shown visible cracks after the construction period. The writer has used his theory of foundation computations in two other buildings with similar results.

The Boussinesq formula derived from the theory of elasticity was used for stress estimates. Predicted settlements have been of the order of 30% greater than observed settlements. The void ratio of clays encountered at these sites is of the order of 9, and compressibility coefficients at the loads usually encountered are of the order of 1 cm^2 per kg. Samples were taken from the top, bottom, and middle of the clay stratum and tested in the writer's private laboratory. The coefficients used were the average weighted values of the data obtained from the three depths.

Concerning the heaving of the foundation, the writer[21] has found that when the excavation extended through the stiff fill underlying the clay, heaving became very noticeable but ceased after a short period. Therefore, the opinion of the writer is that when excavations occur in very soft clay the heaving is mainly in the nature of lateral plastic flow into the excavation rather than an expansion of the underlying clay.

[21] "Aplicación de la Mecánica de los Suelos al Estudio de las Excavaciones en Arcillas Saturadas," by L. Zeevaert, *Ingeniería y Arquitectura*, Agosto, 1942.

Gregory P. Tschebotarioff,[22] M. Am. Soc. C. E.—Two successful foundation designs, based on the principles of soil mechanics, are brought to the attention of the engineering profession by the authors. The time-settlement records of the two buildings, designed by the authors, as compared with the records of three other older buildings founded on similar soil strata at Boston, clearly indicate the advantages of the "floating" type of foundation. Both the maximum and the differential settlements of these two new buildings are much smaller than the ones for buildings with foundations designed in the conventional manner. For a long time Professor Casagrande has been an ardent advocate of the "floating" type of foundations on clays. The behavior of these two buildings, therefore, should give him justifiable cause for satisfaction.

The design of the latter of the two appeals more to the writer. The use of basement walls as stiffening foundation girders provides for a much greater rigidity of the entire structure as compared with the cantilever system used in the first building. This should be of considerable importance in other localities where new designs might have to be made for soil deposits about which fewer data are available than in Boston. The greater general rigidity and the equalizing action of the deep-wall girders should prove very helpful in all cases where the compressibility of a deposit is not entirely uniform. In both buildings, an attempt is made to further equalize the "dishing" effect of deep-seated settlements by increasing the loading at the periphery, and especially at the corners. In the second building, this is done in a very simple manner by decreasing the width of the footings at the periphery and at the corners. The resulting likely variation in the shallow-seated settlements should help in compensating the usual tendency for a greater settlement of the center of a foundation supported by a deep clay stratum. This arrangement, in combination with the use of basement girder walls for load distribution purposes, appears to the writer as being much more economical and effective than the cantilever loading system adopted in the first building with a similar aim. This second arrangement also should be more helpful in counteracting possible harmful effects of any deeper future excavations (for instance, subways) in the vicinity of structures of this type.

The writer heartily agrees with the general Conclusions (1), (2), (3), (5), and (6). However, insufficient evidence is yet available to justify Conclusion (4) that "The settlements due to deformation and recompression following swelling take place essentially during the construction period. * * *" This statement appears to be true under the loading and soil conditions described by the authors, but it does not follow necessarily that it will hold under different conditions. An examination of Fig. 22 shows that the heaving of the bottom of the excavation pit continued without interruption, and even at an increased rate, after the excavation was completed. Only the installation of the foundation slab stopped and decreased the heaving. In the data presented, there is no evidence to show that the heaving would not have continued for an appreciable time had the excavation pit been left open for a longer period. It is reasonable to assume that the heaving of the bottom of the excavation pit is due to two causes: (1) A deformation involving the squeezing of soil into the pit without change of density; and (2) a swelling of the clay as a result of the removal of the overburden. The first cause would predominate in very soft clays, and the greater part of the action should be of relatively short duration. The second cause would be of greater importance in stiffer materials and might last longer. It would appear that, in the case of the Boston buildings, no appreciable swelling could have occurred because of the relatively short period of excavation.

---

[22] Asst. Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

The time element in this kind of work is likely to prove of considerable importance. Gradual absorption of water causes the clay to swell. If this were permitted to occur through a stratum of considerable depth, it is only natural to assume that the settlements following recompression might last for a correspondingly long period and would be much larger. It is not customary to leave excavation pits open for a long time, but it has happened. The writer believes, therefore, that the likely importance of the time element should be emphasized.

Practically no information is contained in the paper concerning the physical characteristics of the clay underlying the two buildings. It is to be hoped that, in their closing discussion, the authors will give this supplementary information. Such descriptions as "hard" or "soft" clay generally are recognized as insufficient to describe a soil properly and in a manner permitting other engineers to visualize its nature.[23] In the paper, the only data concerning the type of clay supporting the buildings described, is contained in Fig. 15, with the clay defined only as "hard" or "stiff" and "soft." No water contents, either in the form of average or limit values, nor any other numerical values of properties important for the visualization and classification of the soil are given. The stratified nature of the clay was mentioned. Therefore, both average values and values related to the coarser and finer thin strata would be of interest. Without such data, the paper will be incomplete, as it will not permit engineers in other localities to relate the observations on their soils to those reported by the authors. It is to be hoped, therefore, that these data will be given in the closing discussion.

The general discussion of the basic soil mechanics principles underlying the design of foundations is presented in a clear and concise manner. There is one point of secondary importance, however, with which the writer does not agree entirely, and which should be stressed since considerable misconceptions have existed on the matter in the past. The authors (see heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils (*g*)") state that the "concentration factor" is no improvement over the theory of elasticity. The reason offered is that when an integration over a finite area is made (using the concentration factor) then essentially the same type of stress distribution results as that shown in Fig. 4.

The writer fully agrees with the conclusion that the concentration factor, as used so far, does not present any actual improvement. However, the very attempt to integrate the concentration factor over a finite area indicates a misconception concerning the physical conditions responsible for the variation of the soil reactions under foundations underlain by sand, as compared with those underlain by clay. In this connection, the writer wishes to point out that the deflection curve of a large foundation resting upon sand, as shown in Fig. 5, does not appear to be correct. Much more likely is the form of the deflection curve shown in Fig. 25(*b*), the idea suggested by the authors being as shown in Fig. 25(*a*).

---

[23] "Exploration of Soil Conditions and Sampling Operations," by H. A. Mohr, *Soil Mechanics Series No. 9*, Harvard Univ., February, 1940, 2d Ed., p. 5.

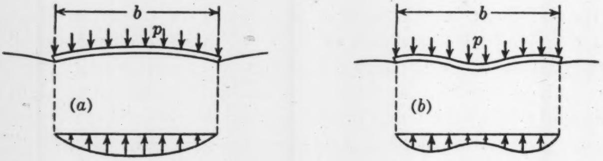

Fig. 25.—Nature of Deflection (*a*) of a Large Uniformly Loaded Flexible Foundation Mat Resting on Sand, and (*b*) the Distribution of Soil Reactions

A zero value of the soil reaction at the edge of a footing underlain by sand is largely due to the fact that the sand can have a shearing resistance only in the presence of a normal stress mobilizing the friction between grains. Such a stress is present under the central part of a footing, but is nonexistent at the edge. In other words, this decrease in the value of the soil reaction is essentially a boundary condition. An attempt to express this boundary condition by the concentration factor can lead to results in agreement with known facts only if the concentration factor is assumed as varying with the distance from the edge of a footing. An integration with a constant value of a concentration factor over the entire area naturally leads to unreasonable results, since the basic assumption underlying such action has no foundation in physical facts.

A large area is likely to deflect in the manner shown by Fig. 25(*b*), since at a certain depth the pressures on a horizontal layer of any soil will be greater beneath the center of a foundation than at its edges. In other words, the effect of the boundary surface condition will decrease with depth, and, for a large loaded area, will be noticeable only at the edges; whereas, beneath the central part of the foundation, the stress distribution in sand should not vary greatly from that of other materials. The point is only of theoretical interest since settlements on sand of normal density are very small in any case.

In conclusion, the writer wishes to emphasize that his criticisms are only of secondary importance, and that the authors are to be complimented on their successful designs.

Guthlac Wilson,[24] M. Am. Soc. C. E.—All engineers concerned with the design of building foundations will find much valuable material in this paper. The writer is particularly interested in the excellent descriptions of two floating or ship-like foundations, a type of foundation that was first brought to his attention by S. E. Faber, M. Am. Soc. C. E., in the course of discussions in Shanghai, China, in the 1930's. It is most interesting to note that this type of foundation is economically superior to the piled foundation even where, as in Boston, a stratum of hardpan is within easy reach of piles.

---

[24] Director, Constructional Design, Ministry of Works, London, England.

However, although in a strict sense the authors are correct, they seem to have been somewhat too sweeping in their statement (see heading, "Examples of the Application of Soil Mechanics to the Design of Building Foundations: The New England Mutual Life Insurance Company Building—Observation of Movements"):

> "* * * Were it possible to distribute the building load uniformly over the building area, and were it possible to excavate and apply the building load simultaneously, no settlement would result. However, it is impracticable to design and construct a building in such a manner that these requirements are fulfilled, * * *."

It appears to the writer that these requirements could be more nearly satisfied, and would be, were it justifiable economically. Assume that a building similar to those described were to be built in another location and that there were no layer of hard or stiff clay overlying the soft clay, as in Boston. The engineer's object would then be to change an overburden of 2 tons per sq ft of organic silt clay and fill at the foundation depth of 40 ft into a uniform foundation pressure of 2 tons per sq ft with the minimum of disturbance. This change could be best accomplished by an adaptation of "The Chicago Method." The outer basement walls and the interior main walls, each with a sufficient area of footing, could be constructed in trenches; the ground floor and a suitable amount of the superstructure could then be built upon these; the basement volume would later be excavated by sections between interior main walls —perhaps each section would be excavated in a series of parallel slices; and the

first basement floor and the main foundation floor could be constructed. As only a small area of the foundation would be opened up at one time, the vertical swelling, or "negative settlement" would be minimized. In extreme cases, it might be worth while to resort to compressed air. The main basement floor could probably be built economically as a series of parallel and continuous barrel-vault arches, designed on the lines of the well-known Zeiss-Dewidag roof. Such an arch of 60-ft span by 30-ft width would bear approximately 2 tons per sq ft if it were 1.5 ft thick. A suggested foundation along these lines is illustrated by Fig. 26.

There is so much information packed into the paper that the writer rather hesitates to ask for more. However, he hopes that the authors will enrich their paper by the addition of information stating what live loads were considered in the foundation computations, what reduction factors, if any, were used, and whether these reduction factors were the same as those used in the design of the columns. Also, they should add diagrams showing the story heights of various parts of the New England Mutual and Liberty Mutual buildings.

W. H. McAlpine,[25] M. Am. Soc. C. E.—The analysis of the design of foundation conditions for the New England Mutual Life Insurance Company Building and the results obtained in the completed structure are of special interest to the writer, perhaps in part because the new structure replaces old structures reminiscent of his school days long ago.

It is noted that, as a result of the settlement investigations, it was decided to use the principle of a floating foundation rather than to carry the load on piles driven through the soft clay stratum into hardpan 125 ft below the ground surface, preliminary plans indicating the former to be the cheaper plan. The decision to adopt the floating foundation plan, in spite of the fact that the surrounding buildings were on piles, must have required considerable courage and a thorough knowledge and confidence in the results of laboratory tests of the soils. Apparently the work in all its steps was planned carefully.

A study of the settlement records appears to justify the foundation plan adopted. The paper emphasizes the importance of both a thorough examination of the subsoils by deep borings and soil tests of the sampled material in connection with the design of foundations for important structures where there is any likelihood of encountering soft material. Too frequently, the mistake is made of being satisfied with shallow borings that fail to disclose soft clay layers at greater depth which often result in serious settlement of the structure. The foundation design of important structures should be based on a thorough investigation of the substrata, taking into consideration the permissible settlement that can take place without impairing the structure. In some cases, considerable inequalities in settlement can be tolerated, whereas, in a gun block for large coastal batteries, any inequality in settlement would be serious. In some instances, taking relative economy into consideration, it may be a close decision as to whether to use piles to carry the load to firm material or to adopt the floating type of foundation.

---

[25] Chf. Engr., Office, Chf. of Engrs., U. S. Army, Washington, D. C.

Referring to Fig. 23, an explanation as to the reason for the greater settlement on the Newbury Street side than on the Boylston Street side would be desirable. Also, a statement as to whether any of the adjacent streets or buildings were adversely affected during or after the construction period would be of interest.

The "Conclusions" of the authors appear sound on the basis of the facts presented.

Karl Terzaghi,[26] **M. Am. Soc. C. E.**—A description of the foundations of two large buildings in Boston, Mass., forms the basis of this stimulating paper. The success of these foundations is due primarily to the fact that the weight of the structures is roughly equal to the weight of the soil removed before the application of the weight of the buildings.

The principle of this simple method for avoiding important settlement of buildings on soft ground has been known for more than a century. It is described in a classical handbook by G. Hagen whose third edition appeared in 1870.[27] After outlining the general procedure, Hagen states that the total weight of the structure should not be greater than the weight of the mass of mud which previously occupied the site of the building. As an example of the successful application of the method he mentions the foundation of the Albion mills in London, England, by Rennie (1761–1821).

In the design of the foundations described in the paper advantage has been taken of the stiffness of the top crust of the Boston blue clay. This procedure was also recommended by Hagen, who quotes as an example the foundation of a ropery in Rochefort in France, designed by Blondel, early in the nineteenth century. The structure rests on a 12-ft layer of stiff mud which constitutes the top layer of a very deep stratum of soft mud.

These examples demonstrate that the most important method at the disposal of present-day engineers, for reducing or eliminating the settlement of structures, is very old. Therefore, many readers of the paper may feel tempted to inquire exactly what contribution to soil mechanics is included in it. To find an answer to this question one may turn to the more recent handbooks—for instance, the German handbook on foundations,[28] published in 1906, which constitutes the successor to the older writings. This more recent and more elaborate treatise does not even mention the method for eliminating the settlement which was well known to the older generation of engineers. The reason is quite obvious: The designs of Rennie and of Blondel originated in flashes of engineering intuition, and the capacity for intuition is not hereditary. Methods of design based on intuition cannot be, and are not, practiced by the average engineer until they become an integral part of a logical system which demonstrates their usefulness on the basis of theoretical principles. Soil mechanics has established such a system.

Still more important is the fact that soil mechanics succeeded in establishing methods for estimating the settlement of structures in advance of construction. Some of the theories on which the computations are based originated late in the nineteenth century. Nevertheless in none of the handbooks on foundations published before 1920 did settlement receive more than casual attention. The consequence of this prevalent ignorance concerning settlement is stored away in the records of countless lawsuits, and they are demonstrated by the curves III to V in Fig. 15. The method for preventing important differential settlements, such as those shown by the curves III to V, was already known prior to 1870, but the designers had no inducement to use it, because they were unable to estimate in advance the settlement of the foundation which they designed. None of the important and spectacular settlements that have come to the writer's attention have been anticipated. They came as "Acts of God." This fact makes the issue clear enough. Soil mechanics did not grow out of the need for novel methods of foundations. It grew out of the urgent need for reliable rules for using the existing ones with less risk. Once the knowledge of the factors that determine the settlement of foundations becomes commonplace, the frequency of inadequate foundations and of surprise settlements will diminish automatically. In other words, in the future, the average engineer will be capable of accomplishing that which, in the past, has been the prerogative of those very few who are gifted with engineering intuition. The average person does not see except that which he has been taught to look for and soil mechanics serves the function of a mentor.

[28] "Handbuch der Ingenieurwissenschaften," III. Band, Der Grundbau, 4th Ed., 1906, W. Engelmann, Leipzig.

In the paper the description of the two Boston foundations is preceded by a set of general statements concerning the factors that determine the settlement of structures. The writer believes that many of these statements require some qualification.

Statements (*a*) to (*m*), under the heading "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils," deal with cohesionless soils. According to the first sentence of statement (*a*), the contact pressure on a rigid area resting on the surface of a cohesionless soil increases from zero at the edge to a maximum at the center. This statement is confirmed by both theory and experiment. However, in practice, the base of every footing is at a certain depth h below the surface. If γ is the unit weight of the sand and ϕ the angle of internal friction, the unit pressure at the edge of the footing can be as great as

$$q_o = \gamma\, h \tan^4 \left(45° + \frac{\phi}{2}\right) \ldots . (2)$$

Therefore the pressure at the edge of a footing is by no means necessarily equal to zero. As a matter of fact, the writer has never seen a record obtained from pressure-cell observations on actual footings which would justify the assumption that the contact pressure along the edge of a footing is equal to zero.

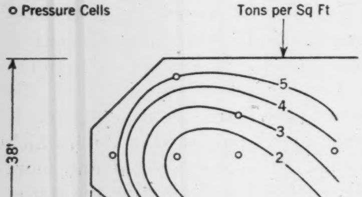

FIG. 27.—DISTRIBUTION OF CONTACT PRESSURE ON THE BASE OF A CONCRETE BRIDGE PIER ON SAND, AT A DEPTH OF 34 FT BELOW THE RIVER BOTTOM

Statement (*b*), illustrated by Fig. 3(*c*), is at variance with the only one set of observations concerning the distribution of the contact pressure on the base of a pier that has come to the writer's attention. Fig. 27 shows the base of the pier, at a depth of about 34 ft below the bottom of the Rhine River. It rests on a stratum of dense, coarse sand with fine gravel. The pier was constructed by the compressed air method. Using the notation indicated in Fig. 3, the value $p = \frac{P}{A}$ was about 4 tons per sq ft and the value $(b + h)\,\gamma$ about 1.8 tons per sq ft. The contact pressure was measured by means of eight pressure cells of the modified Goldbeck type.[29] The lines of equal pressure indicate that the contact pressure increased very considerably from the central part of the base toward the edges. If Fig. 3(*c*) is based on sets of field measurements unknown to the writer, a presentation of the factual data would help in clarifying the issue.

According to statement (*c*) the ultimate bearing capacity of a cohesionless soil increases approximately in direct proportion to the width of the loaded area. This statement is valid only if the coefficient of internal friction (ϕ) of the sand is almost independent of the pressure. Since the ultimate bearing capacity increases approximately in direct proportion to the fourth power of $\tan\left(45° + \frac{\phi}{2}\right)$, a small decrease of ϕ causes an important deviation from the rule which is based on the assumption that ϕ is constant. Therefore, the rule does not apply to sands whose angle of internal friction decreases appreciably with increasing pressure.

The validity of the rule expressed by statement (*c*) has been contested repeatedly, the last time by B. K. Hough, Jr.,[30] Assoc. M. Am. Soc. C. E. According to Mr. Hough, the rule is not in accordance with the results of large-scale field tests. The preceding paragraph leaves no doubt that, in many instances, properly conducted large-scale field tests would disclose important departures from the rule expressed by statement (*c*); yet the writer has not yet seen any reliable record that would either confirm or contradict the statement. The reason is consistently the same: The small footings are loaded to failure whereas the test on the larger ones is discontinued at an earlier stage. The elastic properties of sand are such that the soil support of a footing on sand does not really fail until the settlement exceeds a certain percentage, $n\%$ of the width of the loaded area, regardless of what this width may be. For dense sand the value $n\%$ is about five and for loose sand ten or fifteen. Extrapolation from the load corresponding to a smaller settlement to the failure load cannot be relied upon. In this connection it should be noted that the unit load required to produce a given settlement or a conspicuous increase of the slope of the load-settlement curve has nothing in common with the ultimate bearing capacity referred to in statement (*c*).

Statement (*d*) implies that the ultimate bearing capacity of a loaded area increases with the square of the depth. This statement seems to be open to objections. In the 1920's the writer developed an approximate theory for computing the ultimate bearing capacity of shallow foundations such as circular footings.[4] According to this theory the ultimate bearing capacity q_h of a circular footing with a radius R which rests at a depth h below the surface on a mass of dry sand with an angle of internal friction 36° is roughly equal to

directions. The sand within zone II tends to rise, because it is laterally confined. The rise is resisted by the weight W of the sand within zone III, by the skin friction along the vertical surface of the footing and by the full shearing resistance of the sand along the outer, cylindrical boundary ef of zone III. This shearing resistance is represented by the shaded area efg in Fig. 28(a).

In Fig. 28(*b*), Eq. 3 is represented by the curve N_1. For values of $\frac{h}{R}$ between 1 and 4 the curve is almost straight and it can be represented almost exactly by the simple equation

$$q_h = 1.8 \left(\frac{h}{R}\right) q_o \qquad \left(4 > \frac{h}{R} > 1\right) \ldots\ldots\ldots\ldots\ldots (4)$$

Eq. 4 covers the range of $\frac{h}{R}$ for circular footings. On the other hand, if $\frac{h}{R}$ is greater than 4, Eq. 3 is not even approximately valid. This statement is illustrated by Fig. 28(*c*) which represents a vertical section through a cylindrical pier. Since the height of zone III is great compared to its width, the shearing stresses along ef must necessarily become equal to zero at a considerable depth below the surface, as indicated by the shaded area in the diagram. The average height, $H = n\,R$, of the shaded area depends on the relative density of the sand. In the writer's judgment it may range between zero for loose sand and about $2\,R$ for dense sand. On this assumption the writer obtained the lines N_2 and N_3 for the relation between the depth and the ultimate bearing capacity of the pier. This result suggests that the ultimate bearing capacity increases approximately with depth and not with the square of the depth. As a matter of fact, the writer is unaware of any acceptable theory, or of any record of field observations that would sustain statement (*d*).

According to statement (*j*) the settlement due to a given load decreases rapidly as the depth of the loaded area beneath the adjacent ground surface increases. In order to apply a load on an area at a considerable depth below the surface it is necessary to dig a shaft. While the shaft is being excavated a stress relaxation develops within a zone whose width is several times the diameter of the shaft.[31] In the vicinity of the bottom of the shaft which later constitutes the loaded area and to a considerable horizontal distance from the bottom, the state of stress in the sand is practically independent of the depth of the shaft, provided the depth of the shaft exceeds several times the diameter of the shaft. The settlement of a loaded area depends to a large extent on the initial state of stress in the sand within the zone of potential plastic equilibrium. Since the state of stress in the sand below the bottom of the shaft is practically independent of depth, one would expect that the settlement of a pier at a given soil pressure at the base of the pier should also be practically independent of depth. This tentative theoretical conclusion is illustrated by Fig. 29. According to this figure the ultimate bearing capacity of the pier increases with depth, but the settlement for a given unit load is practically independent of the depth to the loaded area provided the load does not exceed the customary bearing value for the base of piers. The writer's experience in this matter is limited to a large-scale loading test which he made in 1928 on the bottom of a shaft on Houston Street, in New York, N. Y., at a depth of 55 ft below street surface. The bearing block covered the entire bottom of the shaft, from wall to wall. The results of this, and of all the other tests and observations which he made in the shaft, corroborated the opinion illustrated by Fig. 29. Hence they are incompatible with statement (*j*). However, a single set of observations does not justify a final conclusion. Therefore, the writer would appreciate information concerning the field data on which Professor Casagrande's statement (*j*) is based.

[31] "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., New York, N. Y., 1943.

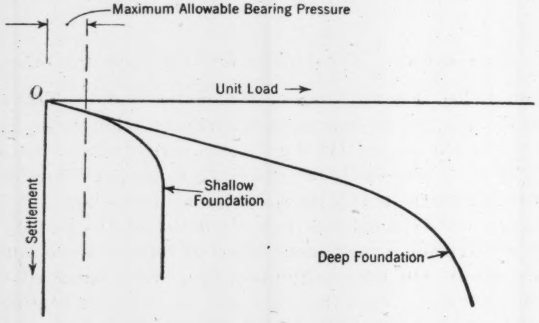

Fig. 29.—Writer's Conception of the Influence of Depth of the Foundation on the Relation Between Unit Load and Settlement of Cylindrical Piers

Under the heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Clays and Other Cohesive Soils," the method for determining the preconsolidation load on clays receives considerable attention. This method was devised by Professor Casagrande in 1936.[32] The text of the original paper conveys the impression that the method is based on the following experimental investigation: Undisturbed samples of different clays have been consolidated in the laboratory under an arbitrary load. Then the load was removed and applied again. The curve which represents the renewed application of a load in the pressure, void-ratio diagram is known as recompression curve. After many recompression curves were obtained a graphical procedure was devised which made it possible to determine the laboratory preconsolidation load, if the corresponding laboratory recompression curve is known. To this point, the procedure was strictly empirical.

The next step consisted in using the procedure without any modification for the determination of a preconsolidation load that was applied by nature at an extremely low rate, thousands of years ago. Although this step constitutes a daring extrapolation, its implications have nowhere been discussed. In order to decide whether it is justified, it is necessary to compare the real value of the preconsolidation pressure produced by nature with those determined by means of the graphical method.

The real value of the preconsolidation load for overconsolidated clays can only be evaluated on the basis of geological evidence but, as a rule, geological evidence regarding the thickness of vanished strata leaves a wide margin for interpretation.

---

[32] "The Determination of the Pre-Consolidation Load and Its Practical Significance," by A. Casagrande, *Proceedings*, International Conference on Soil Mechanics, Vol. III, 1936, pp. 60–64.

On account of the uncertainty of geological estimates the degree of accuracy of the graphical method can be evaluated only on the basis of records pertaining to clays for which the preconsolidation load is identical with the present overburden pressure. This condition is satisfied only for normally consolidated clays. Since these clays have never carried any load other than their own weight, the preconsolidation pressure increases approximately in simple proportion to depth.

In 1936 Professor Casagrande investigated a normally consolidated deposit of glacial clay about 100 ft thick and found that the graphically determined preconsolidation load below a depth of 50 ft is practically independent of the depth, whereas the true load increased in simple proportion to depth from about 1½ tons per sq ft to about 3 tons per sq ft.[32]

Since he assumed that his graphical method is fairly reliable he suggested that the fissured rock beneath the clay may contain artesian water under an exceedingly high hydrostatic pressure. In 1941, D. M. Burmister, Assoc. M. Am. Soc. C. E., published the results of soil investigations of a soft clay deposit at the site of Flushing Meadow Park.[33] Between the depths of about 20 ft and 65 ft below the surface the actual overburden pressure on the clay increased from about 0.6 to 1.4 tons per sq ft. Within the same range of depth the overburden pressure determined by means of the graphical method decreased from 0.6 ton per sq ft at a depth of 20 ft to about 0.26 ton per sq ft at a depth of 65 ft; yet there was no evidence of the presence of artesian water in the sand beneath the clay.

To the writer's knowledge, no other set of data pertaining to drill-hole samples from normally consolidated clays has ever been published. Since the values obtained by means of the graphical method failed to agree with the known values of the preconsolidation pressure for the clays covered by the two published records, it seems unlikely that the agreement should be better in those instances in which the actual preconsolidation pressure is unknown.

On various occasions it has been stated that the graphical method has been applied successfully to the interpretation of the results obtained by tests on shaft and tunnel samples of normally consolidated clays. To eliminate the objection that the favorable results obtained on individual samples may be accidental, it would be necessary to make such tests on a set of samples which have been taken within the same stratum at very different depths; yet, thus far, no data of this type have been published.

The practical implications of the uncertainties concerning the evaluation of the preconsolidation load have been discussed elsewhere by the writer.[34] A systematic analysis of the striking discrepancies between reality and test results may increase, materially, the knowledge of physical properties of natural clays, but this promising source of information has not yet been tapped.

In discussing Fig. 10 the authors state:

> "From a large number of tests on different types of soils, it has been found that the preconsolidation pressure for most clays can be determined with

---

[33] "Laboratory Investigations of Soils at Flushing Meadow Park," by Donald M. Burmister, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 187.

[34] Discussion by Karl Terzaghi of the paper, "Relation of Undisturbed Sampling to Laboratory Testing," by P. C. Rutledge, *ibid.*, Vol. 109 (1944), p. 1196.

> a satisfactory degree of accuracy by means of the empirical method shown in Fig. 10 * * *."

Considering the records quoted, the term "satisfactory degree of accuracy" requires qualification. The writer has used the graphical method repeatedly to determine whether or not a clay has been heavily overconsolidated; but he has ceased to give any weight to the numerical results because both the published records and his own experience indicate that the difference between the computed and the real value for samples from the same drill hole may range between zero and several hundred per cent of the computed value. If the maximum preconsolidation load p_o exceeded the present overburden pressure p_1 by less than a few tons per square foot, the graphical method does not indicate whether p_o exceeded p_1 at all. In such instances, the writer relies entirely on geological evidence. During the seven years since the graphical method was devised, a wealth of data has been accumulated. Therefore the time seems to be ripe for a revision of the method on a broader empirical basis.

Whatever the merits of the present graphical method may be, the research which centered about the preconsolidation load served a useful purpose. It gave an additional impetus to the development of the present methods of sampling and it broadened present knowledge of the physical properties of clays. Many of the refined procedures which grew out of these efforts will become obsolete because it will be found that the required expenditure of time and money is out of proportion to the practical value of what can be gained. Nevertheless the efforts were not wasted because they constitute part of the general exploration of the field and each one of them constitutes one more step toward the ultimate goal. The goal is the development of simple rules and practicable procedures which will reduce the hazards associated with the purely empirical methods of dealing with earthwork and foundation problems.

Under the heading, "Examples of the Application of Soil Mechanics to the Design of Building Foundations," the foundations of two new buildings in Boston are described. In the following discussion the new buildings will be briefly referred to as I (Liberty Mutual Insurance Company Building) and II (New England Mutual Life Insurance Company Building). Building I is supported by cylindrical piers whose enlarged base rests on a stiff clay crust with an average thickness of 10 ft. Fig. 30 shows a vertical section through the base of four piers. The actual thickness of stiff clay crusts is likely to change from place to place and the customary test borings are not numerous enough

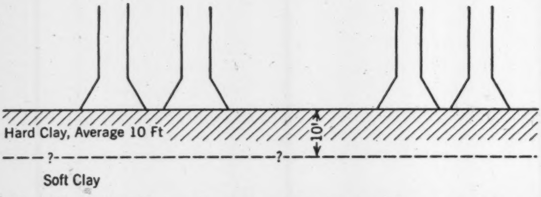

Fig. 30.—Hard Clay Crust Supporting Foundation Piers for Building

for detecting weak spots. The writer would appreciate information concerning the method of surveying the stiff crust or for bridging weak spots.

The foundation for building II was excavated to an average depth of 35 ft. Prior to excavating, eight underground reference points were established in the stiff crust. During the process of excavation the points rose by distances up to 2.9 in. The observed settlement, to date, is roughly equal to the preceding rise of the stiff crust. In 1927 the writer designed a similar foundation. The weight of the building was roughly equal to the weight of the soil and water removed. The excavation penetrated through fine sand to a depth of 30 ft below the surface.[35] At a depth of about 14 ft below the bottom of the excavation the sand rested on the surface of a very thick stratum of soft glacial clay whose water content was close to the liquid limit. Before excavation was begun an underground reference point was established in the sand, a short distance above the soft clay. To the surprise of every one, the rise of the point was too small to be measured with an engineer's level. As a consequence, the settlement of the finished structure was also too small to be measured. However, the writer still believes that the heave of the bottom of the pit was only delayed. If the pit had been open for a couple of months, the heave might have started. Such a possibility is suggested by the well-known delay in the beginning of the swelling of homogeneous clays in tunnels and by the delay of the beginning of the settlement due to the consolidation of clay strata which has occasionally been observed.[36] There are no reliable means for predicting the amount of heave on the basis of test results. If no observations are made, even an important heave may pass unnoticed until it is too late to modify the design or the construction procedure in accordance with the reaction of the subsoil on the change of loading produced by excavation. Therefore the excavation for a deep, floating foundation should not be started without previously establishing a set of underground reference points.

Fig. 18 shows several vertical sections through the basements in building II. It would clarify the concept of the unsymmetrical continuous footings (Figs. 18 and 19(*b*)) if the authors would furnish some data concerning the assumptions on which the computation of the earth pressure on the outside of the basement walls was based.

The description of the two foundations constitutes a valuable contribution to current knowledge of the behavior of foundations on soft soil and it demonstrates again the intrinsic merits of the method of floating foundations.

D. P. Krynine,[37] M. Am. Soc. C. E.—Soil mechanics data concerning sands and clays are summarized in the first part of this interesting paper. These data refer to pressures and settlements and also to the methods of testing. It is regrettable that, in the second part of the paper, which deals exclusively with foundations on clay, this valuable information on sands did not find any application. The discussion hereafter follows the order of presentation of the material in the paper.

[35] "Wellpoint Method for Handling Excavation of Foundation Pit at New Sewage Pumping Station, Lynn, Mass.," by Karl Terzaghi, *Journal*, Boston Soc. of Civ. Engrs., Vol. 14, 1927, pp. 389-397.

[36] "The Actual Factor of Safety in Foundations," by Karl Terzaghi, *Structural Engineer*, Vol. 13, 1935.

[37] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Concentration Factor.—The authors are to be commended for stating very clearly that the principle of superposition is valid only if Hooke's law holds. The so-called "concentration factor" (or "concentration index"), as expressed in Eq. 1*b*, may be applied if the loaded area is very small, as in the highway subgrade. The writer admits that the integration of Eq. 1*b* over large finite areas is decidedly erroneous. A good substitute for the concentration factor is the rule proposed by A. E. Cummings,[38] M. Am. Soc. C. E. If there is a rigid underlying boundary at a depth, z, from the earth surface, the vertical pressure on that boundary may be computed according to the Boussinesq formula using $0.75\ z$ instead of z.

Varved Clays.—Fig. 6 represents a cross section of typical varved clay. It should be added that there are varieties of varved clays in which not two, but three, different materials are combined to form a clay mass. Geologists have studied the origin of varved clays,[39] particularly in New England. Engineering properties of varved clays in New England have been investigated by the U. S. Army Engineers in the Boston (Mass.) District and by the Connecticut State Highway Department, but nothing has been published to date (1943).

Time-Settlement Diagrams.—It is regrettable that Fig. 9 is not discussed by the authors. To the writer's knowledge, time-settlement diagrams, involving the fitting of the curves according to Professor Casagrande's method, have not been treated sufficiently well in engineering literature, and further clarification of Fig. 9 would be important. On the other hand, Figs. 8, 10, and 11 have been discussed adequately elsewhere.[32]

Example of a Settlement Analysis Based on Simple Soil Tests.—A simple method of determining the expected settlement without performing a consolidation test on a given sample is presented in the paper, providing only that results of tests on other clays are available. It is obvious, however, that, in addition to the tests enumerated in the paper, the specific gravity of grains must be determined or assumed.

Caissons.—To the knowledge of the writer, there has been no case of failure of deep-caisson foundations by shear (except, perhaps, during construction). Friction of a deep caisson against the earth mass considerably decreases the pressure on the base and increases the factor of safety. Uniform distribution of pressure at the base of a caisson as in Fig. 3(*c*) is rather a theoretical probability. In reality, because the chamber is filled with concrete at the end of the work, probably there is a slight overloading at the edges of a caisson. An analogous situation is created when tunneling by the liner-plate method. In this case, there is an overloading under the legs of the frame and relief of pressure under the invert.

Differential Settlement Contours.—A uniformly thick clay layer decreases in thickness in proportion to the vertical pressure at a given point. The vertical pressure in the case of a nonrigid rectangular foundation is at a maximum at the middle of that rectangle. Hence, the maximum settlement is to be expected at the middle of a rectangular nonrigid building, especially if the central part of that building is overloaded as in Figs. 16 and 17. There is no way to avoid the settlement completely; but it is possible to decrease its absolute value by making excavations of variable depths and to shift the excess of vertical pressure from one part of the building to another and thus to decrease the differential settlement. The quotation from Professor Casagrande's previous work (under the heading, "Settlements of Buildings in Boston") will stand repeating. It is very true and should be kept in mind by the designers of foundations on clay deposits. In this connection, it is valuable to recall a statement, credited to Glennon Gilboy, M. Am. Soc. C. E., that driving piles into stiff clay is analogous to driving nails into a mirror to reinforce it.

---

[38] "Foundation Stresses in an Elastic Solid with a Rigid Underlying Boundary," by A. E. Cummings, *Civil Engineering*, November, 1941, p. 665.

[39] "Conditions of Formation of the Varved Glacial Clay," by E. Antevs, *Bulletin*, Geological Soc. of America, Vol. 36, 1925, pp. 171–172 (abstract); and other works of the same author and other geologists.

The central contour lines of the differential settlement in Figs. 16 and 17 are elliptical; and the further a contour line is from the center of disturbance (overloaded central part), the less it is elongated and the more it approaches the shape of a circle. This is in accordance with Saint Venant's principle as applied in a horizontal plane.

The Liberty Mutual Insurance Company Building in Boston.—This building has a nonrigid foundation since the load is applied to the clay stratum by numerous caisson bells supporting piers, mats, and columns. Each bell is practically an independent load. For some reason point A, where the maximum settlement has been observed, is located somewhat eccentrically, closer to Stuart Street. This may be due: (*a*) To overloading or (*b*) to a change either in properties or in thickness, or both, of the underlying clay layer. It is very regrettable that in Fig. 17 observed contour lines only are shown, and no information with respect to the forecast settlement is given. This circumstance makes it impossible to judge how close the anticipated values of settlement were to the actual ones and to examine the causes of discrepancy, if any.

The New England Mutual Life Insurance Company Building.—This building differs from the Liberty Mutual Insurance Company in its weight and in the rigidity of the foundation, which, together with the structure itself, represents a rigid box. The building in question furnishes an excellent opportunity to show what a designer and builder of foundations must know about soil mechanics and how this knowledge should be used.

Prior to the final design of the building in question, the following was done:

(*a*) Extensive underground explorations were undertaken and the samples obtained in borings were tested in a laboratory (mostly for consolidation); and

(*b*) On the basis of this information a soil profile was prepared and analyzed. It was found that only two kinds of foundations are to be considered—a "floating" foundation or long piles reaching to hardpan. For economical reasons the former was preferred.

In general, a designer does not need to master the technique of borings and that of laboratory tests; but he must be able: (*a*) To order borings to be made at proper places and to see that they are taken properly; and (*b*) to see that the laboratory makes the proper tests and makes these tests properly. True knowledge of soil mechanics is needed in analyzing the soil profile. However, mere acquaintance with soil mechanics theories, not combined with extensive practice, and especially with what is called "sound judgment," is dead knowledge. In analyzing the soil profile, the designer must be prepared to answer the question: "What might happen to my structure if I build it this way?" Obviously, to answer such a question the Fourier series or the equation of the logarithmic spiral are not helpful. Similar details are required in studying soil mechanics for the first time, but, in applying this study to the design of structures, a thorough understanding of fundamental principles is required; and this can be seen very clearly from the examples of the second part of the paper.

A convincing proof of the necessity of combining theories with considerable practice is the ingenious detail proposed by Mr. Homer, as shown in Fig. 19(*b*). This detail simply could not have been worked out by a theorist without considerable building practice.

If soil mechanics were an exact science (which it is not), no measurement of settlements during and after construction would be necessary. In fact actual settlements would be exactly the same as the settlements exactly computed on the basis of exact soil and load information. In reality, settlements are carefully watched and measured at any project of importance. This is done to check computations made and theories underlying them and also in order to be able to take urgent measures during construction in the case of some abnormality. Particularly the authors are to be commended for the instructive nature of Fig. 22 which, to the knowledge of the writer, is the first in the literature to show both the elastic rebound due to the removal of an old building and the subsequent downward travel of the structure to reach, in the final analysis, the original ground surface.

In conclusion, the writer wishes to congratulate the authors for bringing to the attention of the profession the interesting and important results of their studies on foundations.

O. G. JULIAN,[40] M. AM. SOC. C. E.—A cogent and synoptic thesis on a subject which appears at long last to be emerging into the realm of rationality has been presented by the authors. The differences between soils and what are commonly known as "structural materials" are stated. However, since ultimately all structures are supported on soils (or rock), there appears to be no good reason for not considering the latter as structural materials. Also, it would appear evident that architects and structural engineers who are responsible for the safe and efficient design of buildings should be as well informed regarding the properties of soils as they are regarding other materials such as steel, concrete, brick, wood, etc., on which the stability of their structures depends.

As emphasized by the authors (see heading, "Introduction: Differences Between Soils and Structural Materials"), the statement that a given soil is "safe for" a certain unit load means very little. In addition to the maximum principal stresses, at least the orthogonal stresses and the relationship between stress, strain, moisture content, and time must be considered intelligently; otherwise, the structure may be subject not only to excessive settlement as a whole but to differential settlements which may possibly, in the course of time, wreck the superstructure. The authors correctly emphasize the point that the supporting soil, foundation, and superstructure should be designed as an integral whole. In fact, these components ordinarily form a continuous system which is statically indeterminate to a high degree—the intelligent design of such a system requires knowledge of the properties of the soil and other materials, judgment, and experience to a greater degree than the ability to carry out precise mathematical analyses.

---

[40] Chf. Structural Engr., Jackson & Moreland, Boston, Mass.

It is interesting to note from Fig. 2 the reversal from positive to negative of the change of slope of the strain-stress curve for sand at the point where the major principal stress exceeds the minor principal stress, that beyond this point the slope of the curve for "dense sand" is nearly constant up to the point where the major principal stress is twice the minor, and that dense sand increases in volume with increase in the major principal stress when the latter is three or more times the minor. This latter effect is due to the fact that in order to deform substantially the grains must slip over each other and in so doing cause expansion. The increase in volume indicates that the point of failure is approaching. As appears natural, the "elastic properties" and "shearing strength" of a given sand mass appear to be dependent almost entirely upon the ratio of the principal stresses—that is, on the degree of confinement. A loose liquid sand mass if confined may make excellent foundation material; however, emphasis should be placed on the importance of confining the entire mass. As stated by the authors (see heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils," conclusion (*m*)), serious settlements may result from lowering the ground-water table. Quantitative values pertaining to the curves given in Fig. 2 and definitions of "dense" and "loose" would be most instructive and interesting. It is hoped the authors will publish these data in their closing discussion.

With the exceptions of conclusions (*d*), (*g*), and (*i*), the thirteen conclusions pertaining to noncohesive soils (see heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils") appear to be intuitively evident, at least qualitatively.

Conclusion (*d*) is not evident; it would appear that at least in some cases the ultimate bearing capacity would increase as the first power rather than as the square of the depth. It would be interesting to know whether this conclusion is based on deductive reasoning or was arrived at empirically.

Conclusion (*g*) raises the question as to whether or not the theory of elasticity is valid in any degree when considering the stress or deformation condition of a mass of cohesionless soil. A persual of recent literature on the subject shows considerable divergence of opinion and indicates that the question is at least debatable. Since the theory of elasticity is based on continuity, Hooke's law, and its corollary, the principle of superposition, it would appear a priori that this theory cannot possibly be valid in the case under discussion. On the other hand, it is conceivable that, if subjected to considerable pressure, a confined mass of cohesionless particles may acquire, to some degree, continuity of action and elastic properties so that formulas based on the principle of superposition may be rough approximations and, in the absence of better methods, lead to conclusions that are of considerable value.

According to the theory of elasticity the deformation of an isotropic mass of semi-infinite extent, subjected to a uniformly distributed load over part of the free surface, depends on (1) the shape of the loaded area, (2) the area of the loaded area, (3) the intensity of pressure, (4) the elastic properties of the loaded material, and (5) the rigidity of the structure by means of which the load is applied.

For either a round or a rectangularly loaded area, provided the structure is flexible so that the intensity of loading is uniformly distributed, the average settlement, w_{aver}, may be obtained from Schleicher's formula:[41]

$$w_{\text{aver}} = m \sqrt{A}\, p \frac{1 - \nu^2}{E} \qquad \text{(5)}$$

in which ν = Poisson's ratio; E = Young's modulus; and m = the "shape factor." The latter is a function of the ratio of length, a, to the breadth, b, of the loaded area. The value of m may be determined from the following approximate formulas:[41]

$$m = 0.37 + 0.61\, \epsilon^{-0.052\, a/b} \qquad \text{(6)}$$

provided a/b is greater than unity and less than 100. In Eq. 6, ϵ = base of Napierian logarithms. Approximately, provided a/b is greater than unity and less than 10:

$$m = 0.98 - 0.027 \left(\frac{a}{b}\right) \qquad \text{(7)}$$

For a circle $\frac{a}{b}$ may be taken as unity without substantial error. It may be noted that Eqs. 5, 6, and 7 confirm the authors' conclusion (*i*) as applicable to small areas. Also, as might be surmised from consideration of the resistance due to shearing rigidity, the settlement decreases as the ratio of the perimeter to the area increases.

If the structure is absolutely rigid and the loaded area is circular, Eq. 5 is applicable; but the value of the shape factor[42] becomes 0.89, making the settlement approximately 6% less than the average settlement of a flexible structure of the same shape and weight. From this it may be inferred that the rigidity of the structure has little influence on the average settlement.

Still assuming that the theory of elasticity applies, and further that the structure is absolutely rigid and that the bearing area is round (radius a), the intensity of pressure, q, immediately beneath the structure may be found from the well-known Boussinesq formula,

$$q = \frac{p}{2\sqrt{1 - \left(\frac{r}{a}\right)^2}} \qquad \text{(8)}$$

According to Eq. 8, the intensity of pressure increases from a minimum of one half the average intensity at the center to a maximum at the perimeter; it approaches infinity as r approaches a. This latter intensity, of course, is not realized because the material yields and the pressure is redistributed. By Saint Venant's principle, this redistribution is accomplished without materially affecting the distribution at points some distance from the perimeter. This is well illustrated by Fig. 4(*a*). It may be noted that the distribution of pressure according to the theory of elasticity is the reverse of that which is intuitively evident for a footing on the surface of a sand mass and indicated by Figs. 3(*a*) and 3(*b*). However, comparison of these figures with Fig. 3(*c*) indicates that the slope of the distribution curve decreases at a rapid rate as $(b + h)\,\gamma$ increases and is practically zero for the case where $(b + h)\,\gamma$ equals p. It appears reasonable that further increase of $(b + h)$ would cause reversal of the slope of the distribution curve and that the intensities would approach the values, given by Eq. 8 and represented graphically by Fig. 4(*a*), as the breadth and depth increased indefinitely. Attempts by various investigators to express the variation in intensity, as the properties of the material and degree of confinement of the soil change, have led to the "concentration-factor" (α) concept. In addition to the Froehlick-Griffith formula (Eq. 1*b*),[43, 44] the following empirical formula[45] proposed by D. P. Krynine, M. Am. Soc. C. E., for the case of an absolutely rigid round disk appears of special interest:

---

[41] "Theory of Elasticity," by S. Timoshenko, *Engineering Societies Monograph*, p. 338, Eq. 207; also references on p. 335.

[42] *Ibid.*, compare Eqs. 207 and 209.

$$q = p\left(\frac{\alpha}{2} - 1\right)\left[1 - \left(\frac{r}{a}\right)^2\right]^{0.5\alpha - 2} \qquad (9)$$

in which q, r, and a have the same meaning as in the corresponding elastic Eq. 8 to which Eq. 9 reduces if α is taken as 3. If α is taken as 4, Eq. 9 states that the intensity of pressure is uniformly distributed, as illustrated by Fig. 3(*c*). As α assumes higher integral values, 5 and 6, the distribution curve becomes parabolic as in Fig. 3(*b*) and Fig. 3(*a*), respectively. When $\alpha = 8$, the distribution curve assumes a shape similar to that of a frequency curve. In addition to the aforementioned objections, it appears that the concentration factor, α, itself should be a variable increasing with r and decreasing with z. For example, in the case of a large foundation, the concentration factor for a given depth might be 3 near the center and about 8 as the perimeter is approached. Also, with r held constant, the concentration factor might be 8 near the surface and approach 3 as the depth increases indefinitely. This difficulty, however, might be overcome by a statistical approach—a soil mass of given properties and depth and loaded with a given intensity over a defined area being assigned an over-all constant concentration factor. Not only are careful settlement observations on a multitude of full-sized structures with known underground conditions required, but such observations should be supplemented by pressure-intensity measurements at various depths and horizontal locations. Since the distribution of pressure may change with time, these studies should be extended over a protracted period. F. E. Giesecke, M. Am. Soc. C. E., cites a case[46]

[46] "The Distribution of Soil Pressure Beneath a Footing," by F. E. Giesecke and others, *Bulletin No. 43*, Texas Eng. Experiment Station, 1933.

in which, at the end of the construction period, values of σ_z under the corner and center of the rigid part of a footing bearing on clay were each approximately equal to 2,000 lb per sq ft; but, after the expiration of seven months, the pressure at the corner had increased to 2,240 lb per sq ft and that at the center had decreased to 1,760 lb per sq ft approximately. As stated by the proponents,[47] until sufficient field observations regarding the pressure distribution beneath foundations are made available, formulas such as Eqs. 1*b* and 9 must be considered rather hypothetical. Nevertheless, such formulas appear to be a step in the right direction and may give some idea of the distribution of pressure. Also, it would appear possible to derive corrective parameters which might be applied to elastic settlement formulas such as Eq. 5. However, as has been stated elsewhere by Professor Casagrande[48] in discussing clay masses, the problem is complicated by the introduction of layers of various materials in the underground. The introduction of comparatively stiff diaphragms or slabs, of course, will spread the load and materially reduce the settlement.

Sharp distinction should be made between such materials as sands, which are noncohesive, and clays, which, on account of the "molecular attraction" between the finely divided soil particles and the surface tension of the included moisture, are cohesive and therefore have intrinsic shearing strength even when not subjected to pressure. The clays possess definite elastic properties for loads of short duration; and, therefore, for such loads the distribution of stress and settlements may be calculated approximately from elastic formulas. However, since the major part of the settlement is due to the slow forcing out of the entrapped moisture over a period of many years and, since this process is proportional to the stress to which the soil is subjected, there is a tendency for the distribution of stress beneath a foundation bearing on clay to approach uniformity as time elapses. Either a rigid or a flexible structure supported on clay tends toward convexity downward. In the case of a rigid structure, this may produce stresses of considerable magnitude which should be considered in the design of the foundation and superstructure.

In addition to the elastic settlement which occurs upon application of the load, there may be additional settlement due to plastic and viscous flow.[49, 50] If the working pressure is not excessive, the plastic flow will be negligible; the viscous flow may continue at a diminishing rate indefinitely. Last, but by no means least, there will be settlement due to the entrapped water being forced out of the clay. This effect, due to the highly impermeable nature of the material, will continue at a diminishing rate for many years or even centuries. A method of determining the difference in void ratio corresponding to the difference in pressure caused by the removed overburden and the imposed load, the initial void ratio, and the ultimate magnitude and the rate of the settlement have been described clearly and in detail by the authors.

The foundation design for the New England Mutual Life Insurance Building appears to be almost ideal. Since the design is based on the most certain principle in foundation engineering—that is, buoyancy—it should remove many uncertainties as to probable settlement and magnitude of stresses.

---

[47] "Pressures Beneath a Spread Foundation," by D. P. Krynine, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 846, conclusion 12.

[48] *Ibid.*, Vol. 101 (1936), p. 1119 *et seq.*

[49] "Theory of Heat," by James Clerk Maxwell, Longmans Green, London, 1899, p. 295.

[50] *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 316.

The basic requirement, stated by Professor Casagrande in 1932 and quoted in the paper (see heading, "Examples of the Application of Soil Mechanics to the Design of Building Foundations: General," paragraph (c)), is perfectly sound. To it might be added:

> "Design the foundation and superstructure so that they together may tip slightly but will not bend appreciably under the application of reasonable variations in the intensity of soil pressures."

These principles have been applied by the writer to the design of structures for the support and housing of units of machinery which are sensitive to differential settlement and which, if bent, would be rendered inoperative. In certain cases it may be found advisable to introduce steel trusses in foundation walls. Such foundations are comparable to boats inasmuch as they are, to some degree, buoyant. The New England Mutual Life Insurance Building is comparable to a boat floating on still water.

Without discussing the question of pile foundations in detail, it may not be out of place to mention that the action of a group of friction piles, or piles bearing on an intermediate hard layer under which the soil may yield, is subject to the principles stated in the paper. The soil is subjected to a distributed load of varying and somewhat speculative intensity comparable to that which would be introduced by a foundation mat. The bearing capacity of such a group of piles cannot be evaluated rationally as the capacity of a single pile times the number of piles. Also, since their driving disturbs the clay, a group of friction piles in clay may aggravate rather than minimize settlement.

The authors, in this paper, have made a definite contribution to foundation and structural engineering. It is believed that the value of the paper would be enhanced considerably if, in their closing discussion, they would include a tabulation of range in, and typical values for, void ratios, shearing strength, compressive strength on unconfined specimens, Young's modulus, and Poisson's ratio for clay and other soils.

A. A. EREMIN,[51] ASSOC. M. AM. SOC. C. E.—In this paper the authors have opened an interesting discussion of soil mechanics as applied to foundation design. It is true that correct application of soil mechanics requires experience and judgment. Therefore, a discussion of cases encountered in practice is highly desirable.

Two groups of problems in soil mechanics are generally involved. The first is the distribution of stresses produced by the superimposed loading, and the second is the computation of the resulting deformations in soil, or the settlement of foundations.

Various stress distributions in soils have been classified, the most important being those based on the Boussinesq formula cited in Eq. 1*a*. D. P. Krynine,[52]

[51] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[52] "Pressures Beneath a Spread Foundation," by D. P. Krynine, *Transactions*, Am. Soc. C. E., Vol. 103 1938), p. 827.

M. Am. Soc. C. E., has made a valuable contribution by simplifying the graphical application of the Boussinesq formula, and F. Kögler and A. Sheidig[53] have developed interesting simple methods of computing stresses in soil, the final results of which are in close agreement with that obtained with the Boussinesq theory.

In computing the critical failure stresses in soil, shown in Figs. 13(*a*) and 14(*a*), the authors have assumed that the shear stresses are determined by the horizontal tangent to the circle of stresses. A more exact expression of shear stresses in a homogeneous material is determined from the curved line, or from the sloping tangent shown by S. Timoshenko.[54]

For several reasons, the computation of deformations and settlement yields indefinite results in soil mechanics. The computed deformations can be verified only by measuring the settlements of completed structures, which measurements generally are not readily obtainable. Furthermore, the settlement of a foundation varies not only with the physical properties of the soil, but also with the methods of constructing the foundation. For instance, it is well known that the effect of upheaval in a deep excavation may be reduced by driving the cofferdam sheathing to a greater depth than that generally required for the lateral stability of the cofferdam. Likewise, the effect of upheaval may be reduced by digging the last layer immediately before building the foundation; or it may be reduced by pre-stressing the soil with a temporary loading.

Computation of settlement by plotting graphs of the ratio of voids in soil, as shown in Fig. 12, may produce results that vary within a wide range. In applying this method, the authors did not take into consideration the facts that the stresses in soil vary with a variation in depth of foundation, and also that at various horizontal planes under a foundation the stresses are not uniform.

The authors' conclusion that the settlement of a foundation can be reduced to a tolerable magnitude by removing a quantity of soil which, in weight, is approximately equal to that of the superimposed structure should be considered true only in the case of a limited depth of foundation.

It is true, as the authors state, that the settlement of building foundations is greater in the middle of the structure than that at the walls of the structure. However, the reverse is quite possible. For illustration, reference may be made to experience with the government building in Cairo, Egypt, where the foundations settled less in the middle than at the walls. The Cairo building was designed in 1930, careful consideration being given to the principles of soil mechanics.[55]

D. M. Burmister,[56] Assoc. M. Am. Soc. C. E.—The achievement possible in designing and constructing satisfactory, as well as economical, building foundations by the proper application of the principles of soil mechanics is demonstrated in this paper. The practical value of reliable methods of reducing the total magnitude, and particularly differential settlement, is obvious. No less interesting and important are the actual design features and methods of construction for the two structures analyzed in the paper.

[56] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

In such situations, where the methods described are applicable, the uncertainties involved in settlement investigations may become somewhat less important, and the designer can proceed with greater assurance of satisfactory results on the basis of the available information on subsurface conditions, such as usually can be obtained economically by present methods of soil explorations. For other situations, where these methods are not directly applicable, the uncertainties involved in the settlement investigation may become a major concern in design. It was emphasized by the authors that subsurface conditions cannot be learned in sufficient detail, even by the most elaborate explorations, to serve as an entirely adequate basis for the selection, design, and installation of a satisfactory and economical type of foundation. Consequently, as stated, the results of a settlement investigation should be expressed by a range of values, which include estimates of the possible limits of all factors involved.

The writer considers the following as being the more important sources of uncertainty and error in settlement investigations:

(1) The possible variation in thickness of the compressible stratum between borings from an assumed stratification;
(2) The natural state of stress in the clay deposit or overburden pressure, p_n;
(3) The consolidation properties of the clay;
(4) The foundation stresses in the clay stratum, p_f; and
(5) The settlement characteristics of stratified soil deposits.

Information on the first three items is obtained from subsurface explorations and laboratory soil tests. The sources of uncertainty are due primarily to the necessity of selecting average values on the basis of limited information, and to unknown variations in subsurface conditions between borings which must be assumed, guided by experience in the given area and by judgment. Fairly reasonable values usually can be assigned without much difficulty to the possible limits of variation of these quantities. Their influence, expressed as a range of settlement values in terms of percentage variations from the average, can be estimated by taking partial derivatives of the basic settlement equations with respect to each variable quantity.

In addition to the notation of the paper, let: S = settlement; H = thickness of clay layer; C_c = compression index; C_v = coefficient of consolidation; e_n = void ratio of material in its natural state; p_n = overburden pressure; p_f = foundation stress in the clay stratum; U = consolidation, expressed as a percentage of the total; t = time; T_v = time factor corresponding to values of U; and Δ = variation in any quantity.

For total settlement:

$$S = H\left(\frac{C_c}{1 + e_n}\right)\log_e\left(\frac{p_n + p_f}{p_n}\right) \ldots\ldots\ldots\ldots\ldots (10)$$

and, for time rate of settlement:

$$\text{Settlement (in percentages)} = S\,U \qquad (11a)$$

and

$$t = \frac{T_v\,H^2}{C_v\,(1 + e_n)^2} \qquad (11b)$$

The influence of variations of quantities on settlement is treated as follows:

(1) For percentage variations in thickness ($\pm\,\Delta H$)—

$$\text{Settlement} = \frac{\partial S/\partial H}{S}\,100\%, \quad \text{or} \quad \pm\,\frac{\Delta H}{H}\,100\% \qquad (12a)$$

and

$$\text{Time} = \frac{\partial t/\partial H}{t}\,100\%, \quad \text{or} \quad \pm\,\frac{2\,\Delta H}{H}\,100\% \qquad (12b)$$

(2) For percentage variations in overburden pressure ($\pm\,p_n$, due to possible variations in unit weights or in ground-water elevations)—

$$\text{Settlement} = \pm\,\frac{\dfrac{p_f\,\Delta p_n}{p_n\,(p_n + p_f)}}{\log_e \dfrac{p_n + p_f}{p_n}}\,100\% \qquad (13)$$

(3) For percentage variations in consolidation properties $\left(\pm\,\Delta\,\dfrac{C_c}{1 + e_n}\right)$—

Settlement, variation in reduced compression index

$$= \pm\,\frac{\Delta\left(\dfrac{C_c}{1 + e_n}\right)}{\dfrac{C_c}{1 + e_n}}\,100\% \qquad (14)$$

and

Time, variation in the coefficient of consolidation

$$(\pm\,\Delta C_v) = \mp\,\frac{\Delta C_v}{C_v}\,100\% \qquad (15)$$

These factors actually may combine to produce favorable or adverse combinations, and the actual settlements may be decreased or increased accordingly with respect to the predicted values. Although statistical methods do not help much in arriving at a reasonable probable combination, it is suggested that the square root of the sum of the squares of the percentage variations expressed by Eqs. 10 to 15 will give a reasonable probable range of values, due to a combination of these factors, which may amount to ± 25% to ± 50%, depending on conditions. Variations in conditions at any point influence conditions at all neighboring points because the structure and the supporting soil behave as a continuum. Experience has indicated that the average soil properties in many stratified deposits do not vary as much as one might expect in a horizontal direction within each stratum, although they may vary in a vertical direction in a more or less consistent fashion within the given stratum, due to changing conditions during deposition.

The sources of uncertainty and error under items (4) and (5), which are inherent in every settlement analysis, may be of much greater consequence, because they affect primarily the estimates of differential settlement and the rate of settlement in the early stages, which are needed for appraising the situation as to what should and can be done. These uncertainties arise from the fact that the foundation stresses in natural soil deposits and the settlement characteristics may be quite different from those assumed in the simplified theoretical approach used in the solution of settlement problems. It is difficult and even impossible at present to assign numerical values to the influences of these uncertainties.

The writer is in agreement with the basic soil mechanics principles underlying the design of foundations presented by the authors, but wishes to add a few remarks regarding some of them. Under item (4), the stratification of a deposit, the degree of rigidity of the structure, and the depth of the foundation below the surface of the ground have important influences on the intensity and distribution of stresses in a compressible clay layer. It must be realized that at best the Boussinesq stress equation, as stated by the authors in item (*g*) (see heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils"), can give only a rough approximation for the stress conditions and that the degree to which the law of superposition of stress and strain is valid in a sand stratum overlying clay is open to question. Nevertheless, both represent most important tools in settlement investigations; otherwise, a solution would be impossible. Therefore an assumption of their validity must be made, even though accepted with reservations. It is necessary to distinguish between near surface phenomena in connection with relatively small bearing areas on sand, where the theory of elasticity does not apply, and the intensity and distribution of stresses transmitted through a sand stratum into a clay layer, where the agreement may be much better, provided the solution for a two-layer soil system were known.

Under item (5), the settlement characteristics of stratified soil deposits, both as to total magnitude and rate of settlement, are affected markedly by conditions, because the structure and the supporting soil behave as a continuum. They will tend to adjust themselves in accordance with a kind of "principle of least work," so that the weaker spots tend to relieve themselves of stress and transfer stress to adjacent stronger areas with corresponding adjustments in settlement. The degree of rigidity in the structure tends to reduce differential settlement materially, because the foundations of the actual structure and the supporting soil cannot "follow down" exactly in accordance with the theoretical estimates based on the assumption of individual foundation loads, which are free to move vertically without restraint. The question is: What is a satisfactory measure of the rigidity of a structure, and how much reduction in differential settlement can be achieved economically?

The authors stated in item (*k*) that sand layers provide an excellent medium for spreading load and for reducing differential settlements. The restraints and resistance to deformation of a fairly thick sand stratum overlying a compressible clay stratum also may reduce the total settlement very materially. It is believed that the solution to this problem is best approached empirically from the settlement rather than the stress "angle" by comparing actual settlements with predicted settlements, after making proper allowances for the other factors discussed herein. When a number of structures have been observed for which the subsurface conditions are fairly well known, an empirical coefficient or multiplying factor may be determined by plotting the ratio of the actual to the predicted settlements against the ratio of the width of the structure to the thickness of the reinforcing sand layer. The decrease in settlement with depth below the adjacent ground surface, as stated in item (*j*), may be approached in a similar manner.

In addition to the foregoing factors, which tend to decrease settlement materially, two other factors must be mentioned. Two-dimensional consolidation (see Biot's solution[57]) in contrast to the simplified approach in the one-dimensional theory and the lateral subsurface displacements (lateral bulging effects), which always accompany and contribute to the total magnitude of settlement, may tend to increase settlement somewhat at the walls and decrease differential settlements in the early stages of consolidation.

In order that engineers in other localities may compare their situations with those reported, the authors should include in their closing discussion information concerning the physical properties of the soils in the deposit. It would be of immense value to the engineering profession if the authors would include what they have judged to be the possible variations and the limits for the different factors involved in the settlement investigations and what they have learned from the actual settlement observations of the two structures as a full-scale check on their assumptions as to foundation stresses and settlement characteristics of the deposit.

In conclusion the writer wishes to congratulate the authors on their valuable contribution to applied soil mechanics.

ABRAHAM WOOLF,[58] ASSOC. M. AM. SOC. C. E.—Together with the architects and owners, the authors should be complimented, not only for their excellent study and report, but for their courage in the design and actual construction of a type of foundation radically different from the usual Boston type of foundation. From the settlement results shown in Fig. 15, it is evident that the floating type of deep foundation is the solution to the problem as applied to the conditions in the City of Boston. However, the conclusion that this type of foundation is the general solution in every locality, where at least similar conditions exist, is not justified reasonably. The authors were in a position to assume responsibility for the floating type of design, with the certainty of the resulting settlements as shown in Fig. 15, only after extensive study and observation of the action of several similar structures in Boston. It is to their credit that they correlated their observations and experiences in the field, together with laboratory practice, and prepared a definite procedure for the design of a floating type of foundation. The experience of the authors was the prerequisite to the design. This fact alone should call attention to how important it is for municipalities, universities, and engineers to keep accurate records of the settlements of important structures and also to make laboratory soil tests so that any design which departs from the usual type would be justified in a particular locality.

---

[57] "Consolidation Settlement Under a Rectangular Load Distribution," by M. A. Biot, *Journal of Applied Physics*, Vol. 12, No. 5, May, 1941, pp. 426–430.

[58] Structural Engr., Albert Kahn, Inc., Detroit, Mich.

In underconsolidated clays, such as exist in some parts of Detroit, Mich., there is a possibility that the installation of a floating type of foundation might cause settlements beyond those expected. The character of clays, preconsolidated under loads less than the overburden, presents a problem of sensitive nature, and the floating type of foundation needs careful study if adapted to such clays. The installation of a deep basement, no doubt, reduces the load on the substrata below and at the same time provides sufficient depth to allow for the design of a rigid foundation; but the installation disturbs the firm upper strata and also provides additional drainage immediately below the concrete foundation. The improved drainage increases the rate and amount of consolidation by relieving the excess hydrostatic pressure in the underconsolidated clay. The result, of course, would be increased settlements. However, in normal clays, which are preconsolidated under heavier loads than the existing overburden, no such excess hydrostatic pressures exist, as in the underconsolidated clays, and, even though the deep basement does provide a better drainage under the foundation, there can be no evidence of any additional excessive settlements because the stress condition in the substrata is in balance due to the fact that the excavated loads are approximately equal to the building loads.

Conclusion (5) reads,

> "Differential settlements are best controlled by designing the foundation and the superstructure as an integral unit, with special attention to stiffness. Where this is not acceptable, design for stiffness must be confined to the foundation, which increases the cost and decreases its effectiveness."

This statement becomes of interest to the designing structural engineer because it is his design which controls the internal differential settlements. The writer wishes to classify the differential settlements into two types—the external and internal. External differential settlements are measured at relative points on the periphery of the building, the internal are measured at points within the structure. The purpose of segregating the differential settlement into two types is to help analyze the condition of equilibrium of the foundation, itself, as a structure. The variation in stiffness of a rigid substructure has no material effect on the external differential settlements; but it definitely controls the internal condition. Fig. 23 shows a maximum external differential settlement of 1.16 in. between the two long sides of the building on Boylston Street and Newberry Street, whereas the maximum internal differential settlement on the walls, running crosswise, does not amount to more than 0.5 in. It may be that the Boylston Street subway acts to reduce the settlement rate on the Boylston Street side, thereby increasing the differential on the two long sides. The almost balanced condition of the two shorter sides indicates equilibrium.

The internal differential settlements and resulting distortions are a measure of the shears and moments of component parts of the rigid foundation. In Fig. 23 three of the cross-walls show tension on the top, and the fourth shows tension on the bottom. The writer has spot-checked the wall showing tension on the bottom and found that the moment developed is approximately 635,000,000 in-lb based on a differential deflection of 0.2 in., requiring about 60 sq in. of reinforcing steel at 24,000 lb per sq in. in the bottom of the wall. Since the actual amount of steel installed was not known, it was felt that it would be an interesting check on the original design.

At present, there appears to be no definite answer to the question, "How stiff to make the foundations."[59] A rational approach to the problem would be to design the integral members of the foundation so that structural stability is insured and then to determine what elastic distortions these members will develop under this stability. These distortions can be checked with the soils engineer, and, of course, it would be his responsibility to advise whether the structure is too stiff or too flexible or whether the original assumption of soil reaction distribution needs revision. Also he must decide what adjustment should be made to satisfy the elastic distortion in the soils. The coordination of the instantaneous elastic yield of steel and concrete with the time lag in the elastic yield in clays is perhaps somewhat beyond the present-day developments. Attempts have been made to assume upper and lower limits in the soil and then to interpolate the results obtained by means of reasoning at least to set the direction of the stress.[60] The theory involves the so-called K-values (moduli of subgrade reaction which are given in pounds per square inch per inch), but these values do not introduce the time effect, which is quite important in the analysis of both the structural stability of the foundations and the soil substrata beneath.

In an investigation of recent date regarding the structural stability of a building which had undergone considerable total and differential settlements and still appeared to be sound and not under any serious condition of distress, the following was deduced:

(1) In a distorted, rigid, steel structure, in which the distortions are due to the displacements of column reactions because of settlement, if the calculated stresses in the structure, due to this distortion are at, or beyond, the yield point of the steel, the structure, itself, will undergo elastic relief and these calculated stresses will not exist. The actual stresses in the structure are reduced, by this relief, to the yield-point values or below; otherwise, the entire structure would be in a state of complete collapse, as indicated by the high calculated stresses.[61]

(2) In a concrete structure a similar condition prevails, but the relief is developed by rupture of the concrete in tension, made evident by the appearance of cracks at those points where the reinforcing steel is omitted. The

elastic range between the yield and rupture points for concrete in tension is so close that there is no opportunity for relief to develop without rupture.

These observations are mentioned merely to indicate that, in the design of a rigid concrete substructure, the possibility of a tension stress in the concrete should be eliminated and all concrete members subjected to such possible conditions of stress should be reinforced both top and bottom. The observations also indicate that moderate settlements are not too serious when applied to an analysis of the stability of a structure.

Conclusion (*m*) does not imply that lowering the ground water decreases the bearing capacity of the loose sand. Rather, it refers to the disturbances in the sand structure due to the lowering of the ground water. The writer has made observations where the raising of the ground water has decreased the ultimate bearing capacity of dense sands.[62] The observations indicate ratios for different kinds of sands of $\frac{\text{bearing capacity, dry}}{\text{bearing capacity, wet}}$ as follows:

Item	Grade of sand	Ratio
(*a*)	Nonuniform, well graded	2.83
(*b*)	Uniform, medium grain size	1.98
(*c*)	Uniform, fine grain size	1.52

In Fig. 15(*b*), curve IV is established in its position relative to curves III and V without mentioning the fact that the total settlement of the particular point was known six years after the building was finished and the extrapolation was established for curve IV with those data. In several settlement studies settlement readings were not taken from the construction completion date to the point where the differential distortions become troublesome; and it was impossible to establish the total settlement definitely, particularly where there have been no permanent bench marks and the site immediately surrounding the structure had undergone subsidence. In this connection, it would be of value for any building to establish at least one level of the completed structure definitely tied in with some permanent city bench mark, instead of with a curb, manhole, or any other flexible point. The authors might clarify this point with regard to curve IV.

In discussing Fig. 18(*a*), the authors remark that,

> "It was specified that, if it were discovered, during the progress of construction, that the hard clay in some areas approached the sub-basement slabs, it would be necessary to excavate to a sufficient depth and replace the hard clay by soft organic silt-clay."

The radical deviation from the usual construction practice makes this clause difficult to accept, particularly with respect to the method of backfilling a soft organic silt-clay.

Fig. 19 shows the unsymmetrical footings of the outside walls of the New England Mutual Life Insurance Company Building. The final design indicates a procedure better suited to deep foundations which require a minimum disturbance than to areas outside the building or structure. This type of wall footing is usually standard practice in underpass and open-cut tunnel design. The method of thickening the slab under the wall without indicating structural continuity at the joint between the slab and the wall is not clear. It would be interesting to know the distribution of the soil reaction under this type of footing in order to establish design procedure for the structural stability of the slab and wall.

[62] "An Experimental Investigation of the Relation Between the Bearing Capacity of Dry and Wet Sands," by J. P. Luby and A. Woolf, thesis presented to Massachusetts Institute of Technology, Cambridge, in 1928, in partial fulfilment of the requirements for the degree of Bachelor of Science.

LAZARUS WHITE,[63] M. AM. SOC. C. E.—A large part of this paper is devoted to theoretical soil mechanics, particularly as applying to unconsolidated clays. Considerable valuable information regarding the nature of building settlements and actual records of settlements of buildings in the Boston district are given.

The writer does not wish to discuss theoretical soil mechanics, although he regrets that the use of photoelastic methods as applied to soil mechanics is not mentioned. Also, he regrets that the plottings of the lines of equal vertical pressure beneath the building foundations, described in detail, are not given. For some reason, soil mechanics, as exemplified by the paper, seems to have relegated Boussinesq to the rear and eschewed the graphical representations of pressures so prominent in soil mechanics of only a few years ago. In fact, by a circuitous route, the authors arrive at a conclusion so simple that one wonders whether all the elaborate mathematics of present-day soil mechanics is necessary. All one needs to do, according to the authors, is to excavate from the cellar and subcellar of the proposed buildings a weight of material equal to the weight of the proposed building. The structure can then be erected on mats of reinforced concrete to gain a foundation free of undue settlements, with additional cellar and basement space, all for the cost of a few thousand yards of additional excavation—surely a small price to pay for the benefits realized.

However, in justice to the authors, the writer wishes to call attention to their statement (see first paragraph of "Introduction"),

> "It cannot be emphasized too strongly that the correct application of the results of such an investigation to the design of earthworks or foundations will, in addition to a thorough knowledge of soil mechanics, always require experience and judgment."

This conforms to an old test of any engineering design. Does it conform to good practice?

The writer hesitates to take issue with the authors as to the theories of soil mechanics and confesses that he has been unable to follow the elaborate mathematics of this paper. Nevertheless, there are some basic principles by which to test the conclusions; also, there is considerable experience as to what is good practice. The writer begs to differ with the conclusions of the paper, particularly Conclusions (1), (2), and (6).

---

[63] Pres., Spencer, White & Prentis, Inc., New York, N. Y.

There is an old recognized principle that, in a structure, the loads tend to go to the hard points. As applied to a building with numerous columns extending to cellar grade, the loads can best be picked up by the foundations directly beneath the column bases. The best foundation is based upon this principle. For instance, in the first Chicago (Ill.) "skyscrapers," mat foundations were used on the Chicago clay with unsatisfactory results; then the Chicago caissons were introduced, which carried the loads directly from the columns to hardpan or rock. Later, various types of steel piling and caissons were used successfully. Conclusions (1) and (2) would set the profession back forty years.

When an excavation is made, various disturbances take place. The groundwater level usually is lowered in an irregular way, and, as the authors state, the interior bulges, which may or may not be serious. The placing of sheeting around the exterior of the excavation creates disturbances.

Usually it takes several weeks before the foundation can be completed, during which time the interior is exposed to the weather. It dries out if exposed to the sun, or is saturated if exposed to the rain.

Now if, instead of designing a foundation to carry the loads directly to a secure stratum and by-passing the weak upper stratum, the engineer resorts to a "raft" or "mat" foundation and attempts to avoid differential settlements by an elaborate system of reinforced concrete girders, what risks are run. In the first place, uniformity of pressure is impossible. As amply demonstrated by photoelastic experiments and the application of the Boussinesq formulas, differential pressures bring about differential settlements which may be very damaging. This is covered quite fully in the Progress Report of the Special Committee on Earths and Foundations.[64]

It happens that the Boston clay has been studied intensely over quite a long period, and its qualities are well known; it is geologically a simple formation founded upon hardpan or impervious rock. Calculations of settlements of buildings on Boston clay, computed by the use of the Boussinesq equations and the consolidation test and methods devised by Professor Terzaghi, have agreed fairly well with observed settlements, but nevertheless in other and more complex areas the engineer should be on his guard; consolidation is a drainage problem and the condition must be simple and capable of analysis. However, there are wet areas with difficult conditions, such as that adjacent to the Great Lakes where an oxidized yellow clay prevents upward drainage and an underlying limestone may keep the intermediate soft blue glacial clay under an artesian pressure built up to high values—in some cases by natural gas.

Deposits of clay are often associated with sand pockets under pressure. Such pockets may complicate the drainage of the clay so as to defy computation. Again, an underlying bed of porous limestone may keep the clay under such hydrostatic pressure as to prevent consolidation.

At one location in the Hudson Valley a heavy glacial clay deposit of varved clay is still very soft after a period dating back to the glacial age. This is because the wet blue clay is confined between two layers—an upper, oxidized, very tight yellow clay, and a lower porous limestone under pressure from ground water in a near-by mountain. In the vicinity of Detroit, Mich., a similar condition prevails—an upper crust of yellow clay is underlain by a thick deposit of soft blue clay, also under pressure from a porous layer above the rock floor. For these conditions, the writer knows of no formula which could give the correct rate of consolidation for the blue clay. In both cases, structures placed on the upper yellow clay came to grief—in one case, the blue clay beneath a heavy building squeezed into an adjacent excavation, and in the other case a structure on a heavy mat, in turn resting upon an oxidized layer, settled and upset because of plastic flow in the underlying soft blue clay. The subsoil in any city is subject to changes; it is usually being drained, with lowering of ground water, or a broken water main may cause a rise in the ground-water level.

---

[64] *Proceedings*, Am. Soc. C. E., May, 1933, p. 777.

To the writer, it seems wise to design any important structure with its foundations extended to rock or some deep, sound stratum. There are several methods available. The cost may be a little higher than for a spread footing or mat foundation, but it may prove to be cheap insurance.

The writer has every respect for the authors but does not believe that soil mechanics has advanced far enough to furnish the basis for the design of mat foundations upon unconsolidated strata such as wet clays or silts. Engineers cannot predict confidently what settlements will occur. Such mat foundations are subject to many dangers—from neighboring structures, from neighboring excavations and pile-driving operations, and from the shifting of floor loads.

Methods of installing foundations, particularly to great depths, have been so improved that in most instances the old-fashioned shallow foundations have been superseded. However, in some districts there are thick strata of unconsolidated clays and silts, and the risk of uncertain and irregular settlements of shallow footings must be taken. Soil mechanics may be invoked in such cases to diminish the risk.

Soil mechanics alone is not sufficient for choosing a site or designing a foundation. It is a great aid to the engineer, but not his master. For instance, a building may be "plumped" in the middle of an extinct pond in which, at depths affected by the structure, are layers of unconsolidated peat. Such localities may be detected by the practiced eye of a trained geologist.

The shape of a building is a great consideration in the design of a foundation —whether it is of uniform height or of a tower design, and whether or not it contains courts and projecting wings. Such dangers may be revealed by a plotting of the iso-pressure lines computed from the Boussinesq formula.

GEORGE L. FREEMAN,[65] M. AM. SOC. C. E.—Foundation engineers will find this paper particularly valuable because it follows through, from a statement of the basic principles of soil mechanics affecting the designs, to a description of the "finished products," with records of the settlement phenomena accompanying and following the construction periods. The description of the foundation of the New England Mutual Life Insurance Company Building is of interest, with its record of subgrade heaving and surrounding soil movement, and the adaptation of the construction methods to job conditions. It is obvious that close control of construction methods is essential on such work; otherwise, subsoils and bearing strata may be disturbed and much of the care and skill expended in the design may be nullified.

---

[65] Cons. Engr. (Moran, Proctor, Freeman & Mueser), New York, N. Y.

It may be assumed that the two substructures created by the authors reflect to full extent the benefits of thorough soil studies and their application in the designs. From the performance records, it is evident that both structures have proved satisfactory in service, and the designers are to be congratulated on their success.

The settlements of the belled piers under the Liberty Mutual Insurance Company Building are partly dependent on the thickness and continuity of the hard crust which overlies the deep, soft clay bed. It would be interesting to know what steps were taken to prove the integrity of the crust under each bearing area. The value of the 10-ft hard bearing stratum in distributing load concentrations to the underlying soft clay is evidenced by the regularity and symmetry of the settlement contours in Fig. 17. In both this design and that of the foundation of the New England Mutual Life Insurance Company Building, the designers have taken full advantage of the fortunate existence of the hard crust 40 ft below the ground surface, without which both designs would have been materially different from those shown.

The writer prefers the type of design used for the foundations of the New England Mutual Life Insurance Company Building, as its wall arrangement, if strongly reinforced, can lend great stiffness to the substructure, assisting to smooth out local deflections. Had there been no bearing crust at the 40-ft depth, a full mat design would have been indicated, with the walls modified to some extent to provide proper stiffness.

The provision for future increases in heights of certain sections of the New England Mutual Life Insurance Company Building greatly complicated the problem of designing a floating foundation. With soil excavated, as stated, in an amount to equal the weight of the building, including its future extensions, it would appear that a greater differential of settlement than shown might be expected between the present lightly and heavily loaded areas, unless some compensating factors were introduced into the design. Footing widths shown in Fig. 18(*a*) were apparently designed for ultimate building heights. Would the authors please clarify this point, and indicate the locations of the building sections of varying heights mentioned in the paper?

The tabulation of vertical movements of the hard clay stratum shows that point 5 was up 2.9 in. on October 12, and that other points continued to rise until October 30. It seems from the record that the upward movement must have continued at all points until checked by the weight of the concrete, which was placed in the vicinity of point 5 on October 27. Does not this mean that the area around point 5 might have risen considerably more than the 2.9 in. shown, before the rise was arrested by the weight of the concrete?

The amount and rapidity of the upward movement, prior to the placing of the concrete, leave the writer with a suspicion that a definite soil movement occurred due to lateral plastic flow induced by the weight of the surrounding unexcavated areas, causing uplift of the hard clay blanket. This thought is supported by the fact (see discussion of Figs. 21 and 22) that "the street curbs moved in about 1¼ in. and down about 1¼ in.," with a certainty that the subsidence did not stop at the curbs but extended for some distance over the adjoining street areas. Moreover, it is noted that the total weight imposed on the soft clay at the underside of the hard clay blanket, outside the sheeted area, due to about 50 ft of overburden, was about 5,000 lb per sq ft, whereas the excavation within the sheeted area left a weight of only about 1,600 lb per sq ft to counteract uplifting pressure.

It would be of interest to know how the designers of the two Boston foundations applied live loads in their load-settlement computations. It is the practice in the writer's firm to determine as closely as possible, from the expected occupancy of a building, the live loads that will actually exist, and to use these live loads, plus the actual dead loads, in load-settlement computations. As an example, in the design of the floating foundation for the Albany (N. Y.) Main Telephone Building,[66,67] the total live load assumed in settlement studies amounted to but one third of the total of the designed live loads for the several stories; this was believed to approximate the actual live load contributing to settlement.

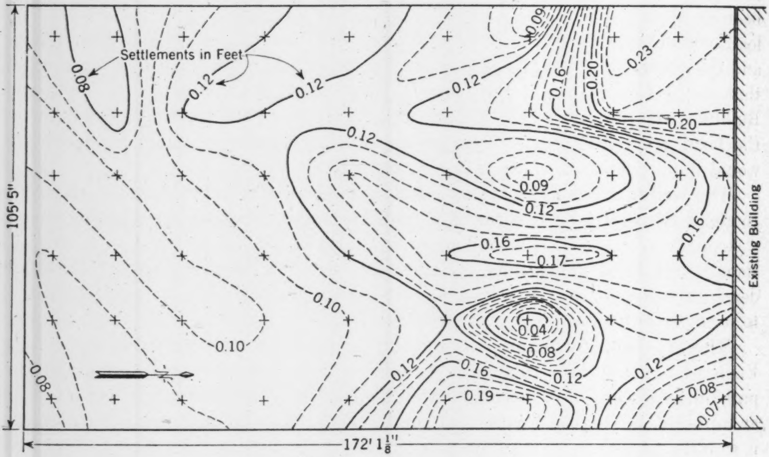

FIG. 31.—SETTLEMENT OF THE FOUNDATION OF THE ALBANY (N. Y.) MAIN TELEPHONE BUILDING AS OF DECEMBER 11, 1930

It is unfortunate that so few settlement records are available, and that those available are so incomplete. The settlement of the foundations of the Albany Main Telephone Building, to December 11, 1930, is shown in Fig. 31. At that time practically all the live and dead loads were on the foundations, the dead load having been in place for practically a year. The south half of the mat

[66] "Rigid Rectangular Frame Foundation for Albany Telephone Building," by G. W. Glick, *Engineering News-Record*, November 27, 1930, pp. 836–838.

[67] *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Vol. 1, p. 278.

settled normally, and about as expected, with corners high and a tendency to dish downward at the center. The north half settled much more, and erratically, due to a cofferdam bracing failure at the north end of the site when the excavation was near subgrade level, more than 25 ft below the ground surface. This illustrates strikingly how the exigencies of construction may upset the calculations of the soil mechanic.

Fig. 32 shows settlement contours, as of February 9, 1927, for the 5-ft thick mat supporting the main office building of the Ohio Bell Telephone Company in Cleveland, Ohio. (The numbers in circles are the settlements, in sixteenths of an inch, extrapolated from records to December 3, 1926, or January 6, 1927.)

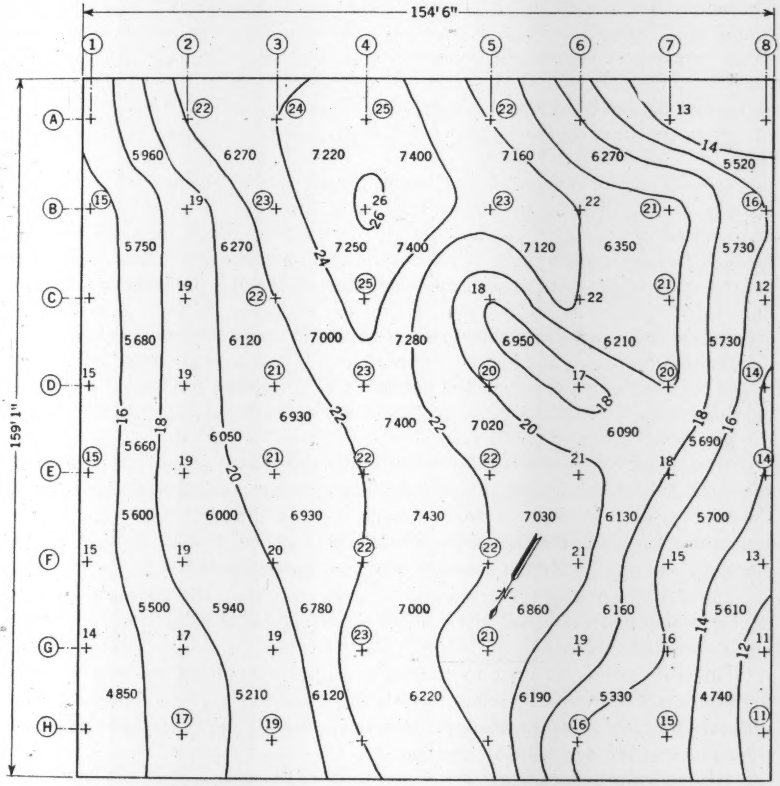

FIG. 32.—SETTLEMENT OF THE FOUNDATION, OHIO BELL TELEPHONE COMPANY BUILDING, AS OF FEBRUARY 9, 1927

This mat is nearly square, and is supported on a great depth of "stiff gray clay." The area had previously been loaded by a theater and a hospital. The bearing level is about 52 ft below the original ground surface, and the mat was designed for varying unit loads, the pressures on the soil being about 5,600 lb per sq ft under the easterly and westerly side panels, and increasing to about 7,400 lb per sq ft in the north and south center panels. (To these loads should be added the uniformly distributed weight of a 5-ft thick concrete mat.) The average intensities of pressure on the soil, exclusive of the weight of the mat, are shown in each panel in Fig. 32, and it will be noted that the settlements followed rather consistently the variation in loading, resulting in a barrel-shaped deflection. The mat was completed in December, 1925, and all foundation work, including three levels of basement space, by March, 1926. Practically all of the dead weight was on the structure at the time of the settlements shown in Fig. 32.

With respect to statements (*a*) to (*m*) (see heading, "Stress-Deformation Characteristics of Cohesionless Soils"), concerning foundations supported on cohesionless soils, it would appear that the general principles outlined are based largely on theoretical considerations, and may or may not apply in practice. Foundations of structures of any magnitude or importance cannot be supported safely at the surface of a cohesionless soil, and are necessarily supported on bearing levels below the ground surface. Under actual conditions, rule (*a*) would not apply.

Rule (*b*) may or may not be applicable for deep caisson foundations. In the absence of data directly bearing on this point, the writer believes that uniform distribution of load over the bearing area is the only assumption that can be made. In the actual sinking of pneumatic and open-dredged caissons to great depths, so many factors upset any calculation of bearing pressures that much uncertainty exists as to the actual pressure distribution in the soil. The excavation in the area of a caisson shaft results in stress release over that area, and, to some extent, outside the excavated area. At the same time, the weight of the caisson, which is supported partly by skin friction and partly by direct bearing under the cutting edges, tends to set up high load intensities around the perimeter of the excavated area.

Subsequent filling and loading of the caissons results in some adjustment of supporting values of skin friction, cutting edge pressure, and direct bearing over the shaft area. In many cases, caissons sunk in granular soils may derive substantial support through side-wall friction, although such support is not generally allowed in the determination of safe bearing areas.

The writer questions the validity of rule (*d*)—that the ultimate bearing capacity of cohesionless soil increases as the square of the depth of the loaded area below the surface.

This rule seems to lead to fantastic results, if applied to very shallow foundations. The writer prefers, from present knowledge, to consider that the ultimate bearing value varies approximately with the depth, rather than with the square of the depth below the surface.

Although the general statements in (*e*) and (*f*) appear sound, the last statement in (*f*) may not be an infallible guide; certainly judgment and experience are required in its application. Settlements do follow the loading of cohesionless materials, and vary with the intensity of loading and density of the supporting soil. Over a large building area the density of the soil will usually vary considerably and differential settlements are to be expected. Load tests will occasionally be advisable to check settlements, especially where high soil bearing intensities are used in the foundation design.

Rule (*j*) may not apply for deep caisson foundations where settlements may be due more to effect of construction operations than to soil characteristics. The writer's experience would indicate that settlement of a deep caisson foundation supported at a safe unit load on cohesionless soil is practically independent of the depth of the bearing level below the surface, and is largely dependent on soil disturbance and other factors connected with the construction procedure.

SOIL MECHANICS COMMITTEE OF THE LOS ANGELES SECTION—TRENT R. DAMES, CHAIRMAN,[68] FREDERICK J. CONVERSE,[69] AND STERLING S. GREEN,[70] ASSOC. MEMBERS, AM. SOC. E., AND PAUL BAUMANN,[71] M. AM. SOC. C. E.—The Soil Mechanics Committee of the Los Angeles (Calif.) Section first read the authors' paper individually and, surprisingly enough, the reaction of each individual was the same. Each felt that the authors had gone too far in publishing a series of brief generalizations regarding the behavior of sand and clay as the publication of generalizations of this nature, unsupported in the text by the data on which they were based and with the exceptions and limitations not stated, may mislead the uninitiated and lead to a loss of confidence on the part of, and the accusation of impracticability by, the construction industry.

When the committee met for detailed discussion of the paper, a new difficulty developed. No two members of the committee were in agreement concerning what the authors intended by some of their statements. For example, under the heading, "Soil Properties Responsible for Settlements," mention is made repeatedly of sand in the loose and dense states without qualification or definition. Sand usually is defined as consisting of more than 80% of particles ranging from 1/20 mm to 2 mm in grain size and the behavior of sands of different composition may be quite different. The division line between loose sand and dense sand presumably is the critical density; the latter, however, is not a soil constant but varies with the moisture content and loading condition and has been defined differently by different authorities. Another example of rather indefinite language is the reference to the "ultimate bearing capacity of a cohesionless soil." It is not clear whether the authors intend the ultimate bearing capacity to be the greatest load which it is permissible to place on a spread foundation or the load that will cause a footing to penetrate continuously through the soil in the manner of a pile being driven. There are several instances in which the authors state that one quantity varies in proportion to another quantity. In some of these cases it is not clear whether the authors are stating that the relationship is one of linear proportion or of some unstated curvilinear proportion.

---

[68] (Dames & Moore), Los Angeles, Calif.

[69] Associate Prof., Civ. Eng., California Inst. of Tech., Pasadena, Calif.

[70] Materials Engr., Bureau of Water Works and Supply, Los Angeles, Calif.

[71] Asst. Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

Apparently the authors intend the statement (*c*) (see heading, "Soil Properties Responsible for Settlements: Stress-Deformation Characteristics of Cohesionless Soils")—

> "The ultimate bearing capacity of a cohesionless soil increases approximately in direct proportion to the width of a loaded area"

—to be the basis for selecting design loads for different sizes of footings. This rule is valid only for a foundation on the ground surface. For footings founded at any depth, this rule does not apply even for the case of final failure. Furthermore, the yield point bearing capacity, which should be used for design purposes, will vary in proportion to the shearing strength of the supporting soil at the depth of the maximum concentration of stress. Statement (*d*)—

> "The ultimate bearing capacity of a cohesionless soil increases approximately as the square of the depth of the loaded area beneath adjacent ground surface"

—is not borne out by the observations of the writers of this discussion. Certain very recent river-deposited sands in the Los Angeles area are capable of supporting, at their yield point bearing value, small spread foundations loaded to 5,000 lb per sq ft at a depth of 10 ft below the surface. Based on the authors' theory, the same deposits at a depth of 50 ft would support 125,000 lb per sq ft, and at 100 ft, 500,000 lb per sq ft. On the contrary, it would be expected that the yield point bearing capacity would vary as a straight-line function of the depth as the support offered a loaded area is a function of the resistance of the supporting material to shearing displacements by lateral or plastic flow. For a uniform soil condition such as the authors evidently are considering, the shearing strength increases approximately in direct proportion to the depth below the ground surface, and therefore it follows that the bearing value would increase approximately as a straight-line function of the depth.[72]

In paragraph (*f*) the statement is made that—

> "* * * for large areas on dense sand, or for areas which are to be founded at a considerable depth below ground surface on dense sand, even the heaviest loading which building codes permit is exceedingly conservative, so far as strength of the soil is concerned, and requires no verification by load tests."

The writers agree that, in general, building codes have restricted allowable bearing loads on dense sand to too low values. However, some advanced codes, such as the new Los Angeles City Building Code, permit deviation from arbitrary allowable foundation pressures after the performance of special foundation investigations. The only requirement of the Los Angeles Code is that "Stresses and deformations within the foundation shall be determined by the general principles of soil mechanics." If building codes impose costly and unnecessary restrictions on construction methods, the codes should be altered.

Statement (*g*)—

> "* * * the fact that Hooke's law does not apply to cohesionless soils also invalidates the law of superposition"

---

[72] "Practical Shear Tests for Foundation Design," by Trent R. Dames, *Civil Engineering*, December, 1940, pp. 784 and 785.

—should be expanded to say "Hooke's law does not apply to any soil." In all soils, the resistance to compression increases approximately as an exponential function of the load, similar to the behavior of metals under compressive stresses beyond the proportional limit.[73] However, the various equations for stress distribution, although certainly not precise, are valuable as an indication of the relative behavior of different sizes and types of foundations.

In paragraph (*l*) it is stated that, for buildings founded on cohesionless soils, borings should be driven—

> "* * * to a depth at least equal to the width of the building * * *."

Here again confusion and uncertainty result from the authors' failure to qualify the meaning of "building." For example, a typical airplane manufacturing building might be from 300 to 400 ft wide by 800 ft or more long with clear spans of 150 ft or more between rows of columns. It is unreasonable in this instance to require that borings extend to 300 or 400 ft in depth.

The authors devote several pages to a consideration of the characteristics of the consolidation diagrams of clay and particularly emphasize the determination of the preconsolidation loads without restricting the statements made to specific clays, such as the glacial clays of New England, or explaining the practical significance and use of the values obtained. The writers have not been able to apply the conclusions and rules cited to the residual and alluvial clays and bay muds of the Pacific Southwest as the consolidation curves of the clays of this region practically never possess straight-line parts on semilogarithmic graphs. The consolidation curves obtained for the clays of this region in general approximate straight lines on double-logarithmic graphs.

In connection with Fig. 13, discussing "Strength of Clay and Safety Against Rupture," the authors state "* * * the possibility of stressing a cohesionless material to the point of rupture practically does not exist." Apparently the authors are referring to a dense, cohesionless soil far below the ground surface, although the limitations intended are not specified. Experience in the design, construction, and behavior of a variety of structures in the Pacific Southwest indicates that the possibility of overstressing a cohesionless material to the point of progressive failure is often the principal consideration. Within the capacity of the soil to resist lateral displacement by plastic flow, the deflection due to consolidation and compression of cohesionless soils (and also dense residual clays) is usually negligible.

In presenting Fig. 14, the authors make the statement that the shear strength of clay "* * * will be equal to a constant c * * *," regardless of the confining surcharge (normal pressure). If the clay is not completely saturated, increased granular pressures will be effective immediately upon application of load, and the shearing strength therefore will increase with the confinement and be expressed by the equation,

$$s = c + n \tan \phi \qquad (16)$$

---

[73] "Recent Work in the Field of High Pressures," by P. W. Bridgman, *American Scientist*, January, 1943, Fig. 15.

in which s is the total shearing strength; c, the apparent cohesion; n, the confining surcharge; and ϕ, the apparent angle of internal friction of the soil. For clays of this region, while the apparent angle of internal friction, ϕ, may be as low as 3° or 4°, it may also be as high as 20°.

In further discussing Fig. 14(a), the statement is made "* * * that the pressure q_o, which the footing must exert in order to produce failure * * * is equal to $4\,c$." By the use of another theory quoted, q_o was equal to $5.5\,c$ and again,[10] $5.14\,c$. Apparently, the authors are considering the conditions of final failure which is reached at considerably higher loads than those at which initial yielding occurs. The load which would produce this final failure would certainly not be a desirable basis for determining an allowable design load. A better appreciation of the behavior of loaded soils may be obtained through a study of the stresses required to produce yielding and plastic flow.[74,75] The yield point of a semi-infinite body loaded by a circular area on its surface is equal to π times the shearing strength. The ratios of unit load to shearing strength for other shapes of loaded areas do not vary appreciably from π. Practical confirmation of this relationship has been secured over a period of years.[72]

In the last few paragraphs under "Soil Properties Responsible for Settlements," the authors recommend the performance of cylindrical compression tests to determine the bearing capacity of clays. It is not clear whether the authors are referring to the use of triaxial compression tests or compression tests on unsupported soil cylinders. The authors, of course, realize that tests on unsupported soil cylinders are frequently impossible because of the character of the material. The direct shear test may be used effectively for all kinds of materials, without exception, and offers a means of determining bearing capacity with sufficient exactness for practical purposes at a cost which is comparable to the free cylinder test and which is much less than that of the time-consuming triaxial test.

The statement in the very last paragraph under "Soil Properties Responsible for Settlements" that, in the case of caisson foundations, "the hydrostatic uplift of the soil may be added to the foregoing value of $5\,c$ and used as the ultimate bearing capacity" is very dangerous and subject to a long series of limitations most important of which is that the bearing capacity given by this rule is actually the capacity at ultimate failure and not a basis for allowable design loads.

The value of the second part of the paper, "Examples of the Application of Soil Mechanics to the Design of Building Foundations," would have been much enhanced if the authors had included information on the physical characteristics of the soils upon which the buildings in question are founded as this would enable the reader to make a comparison with similar soils, the behavior of which had been studied and experienced. The only such data, so far as the writers are aware, is that shown in Fig. 15 (a), which appears to be reminiscent of the usual well-driller's log except for the fact that it gives no record of ground water. Above all, it is the clear and specific identification of the foundation

[74] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1934.

[75] "Plasticity," by A. Nádai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931.

soils which the writers (and probably many other readers interested and somewhat familiar with soil mechanics) hope to find in papers of this nature. Under the circumstances, this part of the paper, although definitely intriguing, is not as enlightening as it could be.

In closing, the writers hope that their discussion will be accepted as constructive criticism. They are well aware of the difficult, even impossible, task of setting down theories and principles of soil mechanics in the form of generalities, which have many exceptions, without the time or space for adequate discussion of the exceptions or clear statements regarding the limitations of the generalities.

A. CASAGRANDE,[76] M. AM. SOC. C. E., AND R. E. FADUM,[77] JUN. AM. SOC. C. E.—The discussions, which represent much thought and labor on the part of the contributing engineers, are very stimulating to constructive thinking. Careful study of their contents is recommended to all who are seriously interested in this subject. In addition to presenting a great deal of new material, the discussions contain a divergence of views which should encourage the development of independent thought so important in this field in which design is still largely dependent on judgment.

The discussions have broadened the scope of the paper to such an extent that the authors are not able to comment in this closure on all the new material presented, nor to answer all of the many requests for additional information. In the following, emphasis is placed on material which would not otherwise be available to the readers.

PROPERTIES OF CLAYS AFFECTING SETTLEMENT ANALYSES

The numerous requests in the discussions, for detailed information on the properties of the clays underlying the buildings described in the paper, prompted condensed use of material originally intended for a separate, comprehensive publication on this subject. In this form it also serves as an answer to comments on methods developed by the senior author for analyzing the preconsolidation pressure of clay deposits.

General Description of the Boston Clay Deposits.—The clays underlying Greater Boston are probably among the best explored and most thoroughly tested clays for foundation purposes. They have served as a proving ground for much research in soil mechanics and also for the development of soil sampling methods. In particular, the explorations for the two buildings described in the paper have assisted greatly in improving soil sampling tools and methods. This development culminated in the best sampling of this clay so far accomplished—namely, the samples taken during the explorations for the Mystic Power Station of the Boston Edison Company during 1941–1942. Because considerable trouble in undisturbed sampling was still experienced at the sites of the two buildings referred to in the paper, for which the explorations were conducted from 1936 to 1938, the results of explorations at all three sites will be presented. For the sake of brevity the sites will be referred to as follows:

---

Site	Building
I	Liberty Mutual Insurance Company Building
II	New England Mutual Life Insurance Company Building
M	Mystic Power Station

At all three sites the soil profiles are similar. Directly overlying rock is glacial till, sand and gravel, deposited and pre-loaded by glaciers. Overlying this material is a thick stratum of inorganic clay, water deposited during the retreat of the last ice sheet. This clay is a fairly continuous formation, but contains many lenses of sand and local pockets of gravel and boulders. Except for the upper hard crust, which at one time was exposed to surface conditions (drying and oxidation), the color of the clay varies between darker and lighter shades of olive green and gray. The term "blue clay" should not be taken literally. This simplified color designation has become part of the name of this clay.

The effect of the drying of the surface has produced the so-called "hard yellow clay" which again is an exaggerated color designation. Beneath this hard clay there is a gradual transition into stiff and medium and finally into soft blue clay.

Because of irregular erosion, the thickness of the hard yellow and stiff blue clay is variable. Over limited areas these materials are entirely absent, and in some places sand has been deposited in their stead.

After this period of drying and erosion, the land subsided again during the past five thousand years or so, bringing the surface to an average El. −20 mean low water (M.L.W.). On top of the clay a deposit of organic silt was formed, averaging 20 ft thick, and this was finally covered by artificial fill as thick as 20 ft. The thickness of the soft clay averages between 50 ft and 100 ft. This clay deposit is chiefly responsible for building settlements in Greater Boston.

The physical characteristics of good undisturbed samples of the blue clay vary between a very brittle material which upon remolding becomes extremely soft and sticky and a material that shows no brittleness, upon remolding softens much less, and does not become sticky. To distinguish between these extreme types, they will be referred to as "brittle" and "plastic" types, respectively.

The brittle type is easily sampled with thin-wall samplers,[78] the clay practically "melting" under the pressure of the cutting edge. Such samples show no bending of the bedding planes, although improper sampling may result in shear planes. Even rather stiff soils of this type can be sampled with little pressure and can be easily pushed out of the tubing. This type usually has a slightly more greenish color than the plastic type.

The plastic type offers much more resistance to sampling and to the removal of the samples from the tubes, although the samples may be only medium soft. Even with the best sampling procedure in bore holes some bending of the planes of stratification cannot be prevented. This type of clay often contains individual larger grains of sand and here and there a pebble. It is usually less regularly stratified, and sometimes mottled, as if at one time the deposit had been badly disturbed. Also, it is often found adjacent to boulder nests or lenses of sand or gravel.

---

[78] "Exploration of Soil Conditions and Sampling Operations," by H. A. Mohr, *Soil Mechanics Series No. 21*, Harvard Univ., Cambridge, Mass., 3d Ed., November, 1943.

In addition to these extreme types there are intermediate types which exhibit some brittleness. Since the grain-size distribution and the liquid and plastic limits of all types vary within the same general range, no differentiation is possible by means of such classification tests. The raw material seems to be the same. Differences in intensity of flocculation at the time of deposition (in other words, differences in the structure of the clay) are assumed responsible for the wide variations in physical characteristics. An attempt was made to determine from the contents of Foraminifera whether individual samples are marine or fresh-water deposited. H. C. Stetson, of the Department of Paleontology at Harvard University, Cambridge, Mass., found Foraminifera in all types of the Boston blue clay, but very sparse (only three or four individuals to about 40 g of dry clay), indicating that the deposit might have been laid down in an estuary at some distance from the sea, under brackish conditions.

The distribution of plastic and brittle type clays over Greater Boston shows no regularity. For example, in the Lynn area the highly brittle type, with a natural water content at about the liquid limit, is present at El. −40, whereas at the same elevation in other areas the less brittle types are usually found. (Elevations refer to Boston city base unless they are marked M.L.W. Boston city base is 6 in. below M.L.W.) In the deep borings at site M the plastic and brittle types alternate. At one location in Cambridge the hard yellow clay was distinctly of the brittle type. Yet, in spite of its hardness, it was considerably above the plastic limit and became medium soft upon remolding. From these and other observations it was concluded that, at the same time and with the same raw material, brittle types of clay would appear to have been deposited in some areas and plastic types in others.

At several sites the brittle type predominated near the bottom of the soft clay stratum. This order of occurrence may be responsible for earlier conclusions that the Boston clay at greater depths is extremely soft and not yet fully consolidated. Actually, good undisturbed samples of such brittle clay, from depths of about 100 ft, have been found to have compressive strengths up to 2 tons per sq ft; but the use of thick-wall samplers, and the practice of unwatering the bore holes, creating great unbalanced stresses in the clay to be sampled, resulted in such serious disturbance to the samples that, upon recovery, they had to be classified as very soft. This condition, together with the fact that sampling operations become unwieldy and time consuming with great depths, has generally resulted in samples being increasingly more disturbed with greater depth. The use of thin-wall samplers of 2-in. and 3-in. diameter, operating in water-filled, cased bore holes, has eliminated most of these difficulties. Excellent undisturbed samples of brittle clay were obtained at site M from depths as great as 120 ft.

The practice adopted by boring contractors of classifying the consistency of the clay, according to the driving resistance of the sampling tube, as hard, stiff, medium, soft, and very soft, does not reflect the type of clay. The designation "very soft" may actually refer to a medium stiff, very brittle type of clay which "melts" under the concentrated pressure of the cutting edge.

MYSTIC SITE

Variations in Water Content and Plasticity in Boston Clay.—The great variations in natural water content can be analyzed by relating water content to the liquid and plastic limits.

From hundreds of limit determinations of samples obtained at many sites in the Greater Boston area the total range of variation for the liquid limit was found to be 30 to 76; and for the plastic limit, 16 to 33. Omitting the very exceptional values, an average range of 40 to 55 is found for the liquid limit; and one of 20 to 25, for the plastic limit.

For sites I, II, and M, for which very detailed soil investigations were made, the average arithmetic means are as follows:

Site	Liquid limit, L_w	Plastic limit, P_w
I	48.3	23.8
II	48.0	22.6
M	45.6	22.3

The over-all average for the liquid limit is 47; and for the plastic limit, 23.

The most complete record yet available in the Boston area for a deep boring is illustrated in Fig. 33, from site M. Fig. 33(*a*) shows the natural water content w_n, and limit values L_w and P_w, and Fig. 33(*b*) gives the so-called water-plasticity ratio (percentage),

$$B = \frac{w_n - P_w}{L_w - P_w} 100 \qquad (17)$$

which gives the relation of the natural water content to the limits. For $w_n = P_w$ this ratio is 0%, and for $w_n = L_w$ the ratio is 100%. Values greater than 100% indicate that the natural water content is above the liquid limit. In Figs. 33(*a*) and 33(*b*), the solid line denotes the theoretical distribution of water content w_n and B, respectively, computed from the average laboratory virgin compression curve, shown subsequently as curve T in Fig. 36.

For sites I and II the B-values are plotted in Fig. 34. In this diagram observations also cover a range in elevations for which no values are available in Fig. 33 because of loss of samples.

The spread in the B-values in Figs. 33 and 34 is not entirely due to variations in the type of clay but, to some extent, is the result of inaccuracies in correlating the water content and limit values.

Fig. 35 shows the results of the most recent tests of this type, determined from samples obtained from a boring in Boston Harbor. Special care was taken to make sure that water content and limits were determined from identical material, and also that lean and fat clay layers were not mixed. To check the latter, the different color shades were used as a basis for differentiation. When the tests for Figs. 33 and 34 were made, the importance of such extreme care was not fully realized.

Fig. 35 does not represent the full range of variations in water content, since every determination is the average for a height of several inches. By slicing the clay into thin layers, sometimes a value as low as 25% is obtained for a thin layer of light colored very silty material; and a value as high as 60%, for a dark olive greenish clay layer.

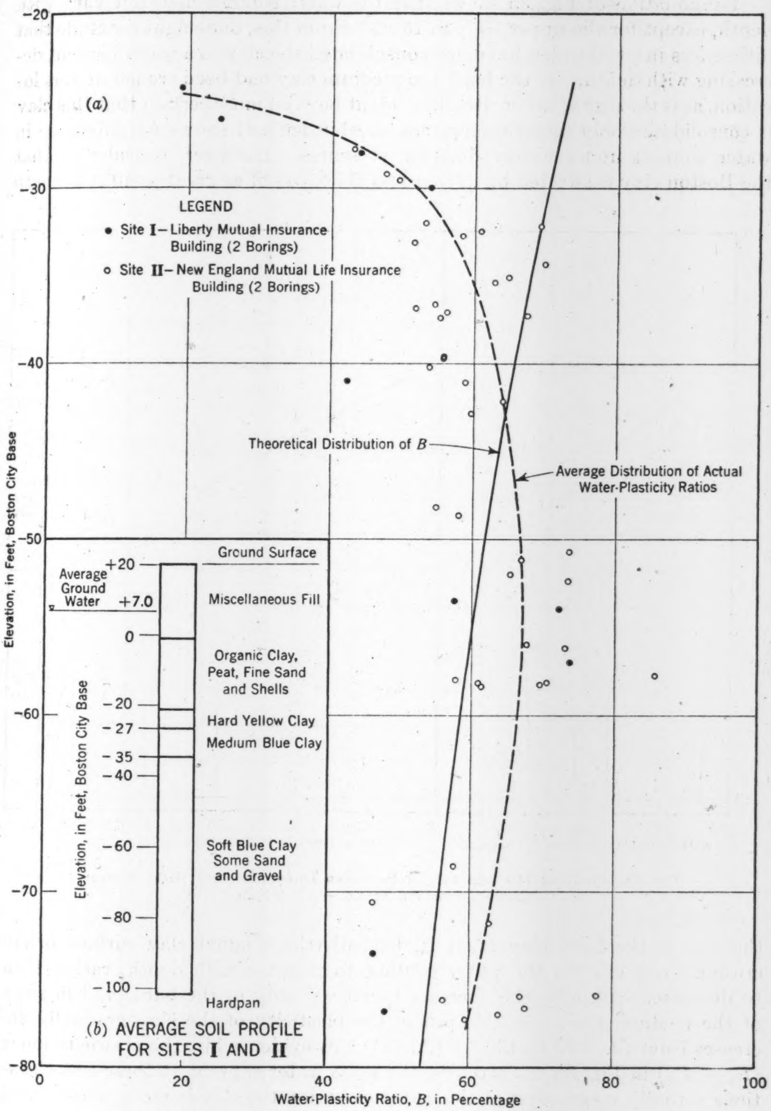

FIG. 34.—WATER-PLASTICITY VALUES FOR BUILDING SITES I AND II

Examination of Fig. 35 shows that the water content does not vary with depth, except for the upper 10 ft to 15 ft. From this, one might conclude that differences in overburden have not consolidated the clay to a water content decreasing with depth. If the hard and medium clay had been eroded at this location, as is the case at other sites, one might be even more certain that this clay is consolidated only under the present overburden and shows no difference in water content under widely differing pressures. However, considering that the Boston clay is affected by drying to a thickness of as great as 40 ft beneath the top of the hard clay (that is, beneath the original clay surface before erosion), one expects the water content to increase with depth, rather than to decrease. Actually this increase is noticed only in the hard, and in some of the medium clay. At this profile the plasticity of the clay gradually decreases from El. −23 to El. −40 M.L.W., as evidenced by the plasticity index ($L_w - P_w$) in Fig. 35. Therefore, the same water content at these two elevations actually means that at the upper elevation the clay is more consolidated than at the lower elevation. In this case, only a study of the relation of the water content to the limits—that is, of the water-plasticity ratio—can assure correct interpretation of the meaning of the constancy of the water content

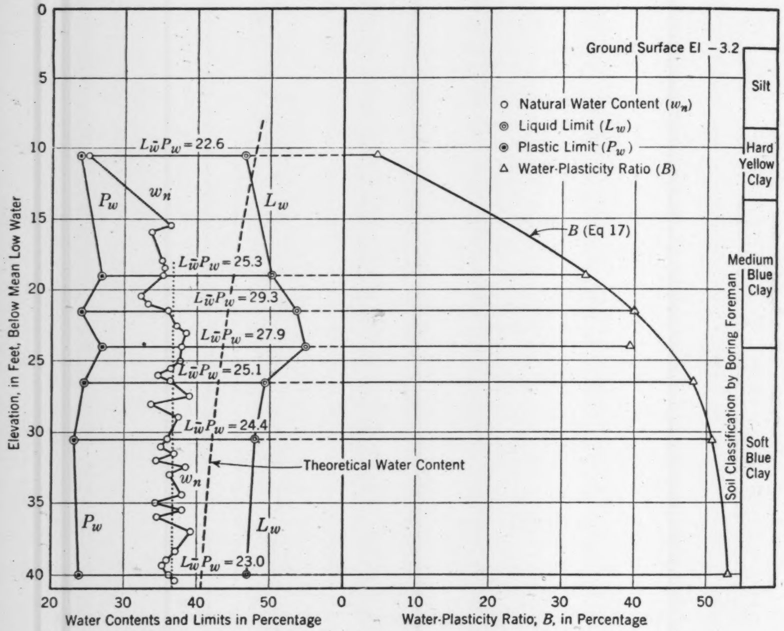

Fig. 35.—Borings 14A and 14B in Proposed Dredging Area, East Boston (Ground Surface at El. − 3.2 M.L.W.)

with depth. A study of the water content alone would lead to erroneous conclusions.

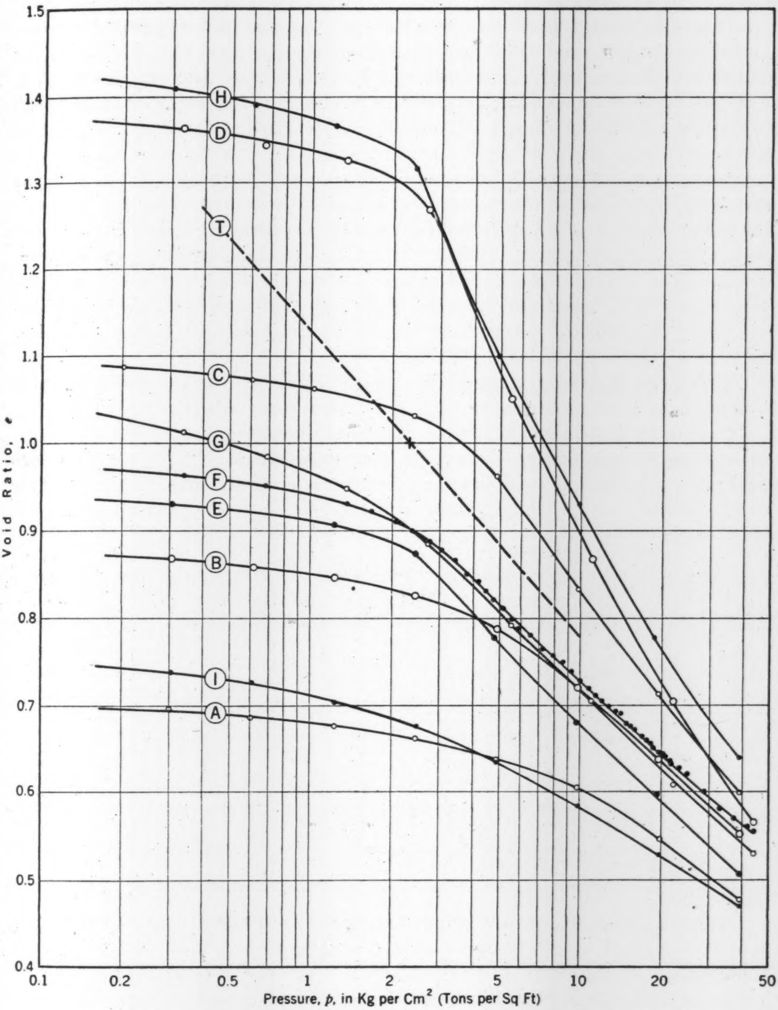

FIG. 36.—TYPICAL PRESSURE VERSUS VOID RATIO CURVES OF BOSTON BLUE CLAY FROM UNDISTURBED SAMPLE BORING NO. 3, MYSTIC SITE

Water Content of Hard Yellow Clay.—During remolding of an undisturbed sample the water content of the hard yellow clay may appear to be slightly below the plastic limit, because the clay crumbles before it can be molded into a thread. However, the plastic limit of the same sample, after it has been remolded with water for the determination of both limits, is actually slightly below the natural water content, with the corresponding B-value between 0 and 20%.

This discrepancy between the "feel" of the material remolded from an undisturbed state, and the "feel" of that which has been kneaded with the addition of water, has been noticed also for other clays near the plastic limit. Apparently, remolding of hard clay with the addition of water effects a thorough breakdown of the structure, which mere remolding at the natural water content will not accomplish.

Consolidation Tests and Preconsolidation Pressure for Boston Clays.—Fig. 36 shows typical pressure versus void ratio curves for undisturbed samples from the same boring for which other test results are assembled in Fig. 33. The preconsolidation pressure p_p for each curve, determined by the graphical procedure, as well as the probable range of p determined from the shape of the transition curve, is given in Table 1. Generally, the more brittle a sample, the sharper is the transition curve between the recompression and virgin branches, and the narrower is the estimated range for p_p.

The virgin curves are generally straight lines on a semilogarithmic plot, except those for samples with initial void ratios considerably greater than 1.0.

Curves D, E, F, and G, Fig. 36, were obtained from specimens only a few inches apart in elevation. Curve D corresponds to a specimen with a high natural water content, whereas the other three curves represent another type of clay with a water content approximately equal to the over-all average of this boring.

T	Average (e–p)-curve for the computation of the theoretical distribution of w_n and B (see Figs. 33, 34, and 35)					

Curve E, Fig. 36, was obtained from a standard test that lasted one week, whereas curve F was obtained from a long-time test that lasted 85 days. Comparison of the shape of the (e-p)-curves and of the preconsolidation pressures, obtained from them, indicates essentially the same results. These two tests, and similar comparisons on other clays, permit the conclusion that consolidation tests lasting several months give practically the same results as the standard tests performed in a few days.

Curve G shows a rather steep recompression branch and a flat transition curve to the virgin branch. This condition is usually caused by excessively distorted samples. For comparison the results are included, showing that the preconsolidation pressures obtained from this test are about 20% to 25% lower than those from the other three tests performed on specimens from the same elevation.

The preconsolidation values obtained from the twenty-four tests on undisturbed samples from this boring are plotted in Fig. 33(*c*), and for comparison the actual stresses under the present overburden load are shown. From the surface of the clay stratum to about El. −65 the clay appears to be consolidated by drying. Below this elevation there is a good agreement between the p_p-values obtained from the tests and the actual overburden pressure, indicating that the soft clay below about El. −65 may be considered consolidated under the present overburden load. In this case there is fairly clear geological evidence that overburden was never higher than at the present time.

The importance of great care in the performance of consolidation tests, if they are to be used for analyzing the preconsolidation pressure, cannot be overemphasized. Such tests should be supervised and checked carefully, since irregularities in loading, differences in the time allowed for each increment if not adjusted to the same period, etc., easily cause changes in the shape of the $(e–p)$-curves which may result in large errors in the derived p_p-values. Tests in which some or all increments were not allowed to stand long enough to develop the slope of the secondary compression curve clearly, as indicated by semilogarithmic plots of the time curves (see Fig. 37), should be discarded.

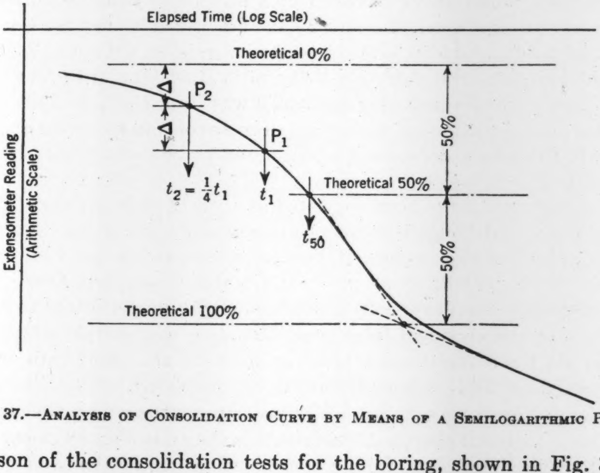

FIG. 37.—ANALYSIS OF CONSOLIDATION CURVE BY MEANS OF A SEMILOGARITHMIC PLOT

Comparison of the consolidation tests for the boring, shown in Fig. 33, with older tests on samples of Boston blue clay obtained with thick-walled samplers indicates that the general magnitude of the preconsolidation pressures, determined by the shape of the $(e–p)$-curves on less perfect samples, is still of the correct order of magnitude,[79] but that the error in the graphical procedure may increase to 50%.

---

[79] "Relation of Undisturbed Sampling to Laboratory Testing," by P. C. Rutledge, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1155.

Comparison of Actual and Theoretical w_n-Values and B-Values for Boston Blue Clay.—Fig. 33 also shows the theoretical decrease of water content w_n and water-plasticity ratio B with depth, computed on the basis of an average laboratory compression curve, shown in Fig. 36 as the broken line T ($C_c = 0.355$, through $e = 1.0$, or $w_n = 36.3\%$, and $p = 2.3$ kg per cm²).

For the zone below the influence of drying, the theoretical decrease in water content from a depth of 80 ft (El. −63.4) to a depth of 120 ft (El. −103.4) is from 36.8% to 34.4%. This decrease is so small that it is completely overshadowed by the actual variations in water content. For the same depths the theoretical B-value (assuming $L_w = 47$ and $P_w = 23$) is reduced from 58% to 48%. The actual decrease in B-value is much greater than the theoretical decrease.

Investigations of Other Clays.—The Laurentian clays permit study of a large range of preconsolidation pressures. The hard Laurentian clays, investigated by Irving B. Crosby, Affiliate Am. Soc. C. E., and the senior author in 1930,[80] are preconsolidated under pressures of from 7 to 15 tons per sq ft, whereas the soft Laurentian clays investigated in recent years by the U. S. Army Engineers are consolidated under pressures of only 1.0 to 1.5 tons per sq ft. Both types of clay are of marine origin and are extremely brittle in the undisturbed state. When remolded, the hard clay becomes very soft and sticky, and the soft clay changes practically into a fluid. Grain-size curves and the Atterberg limits fall in the same ranges. The liquid limits for the hard clay were found to lie between 29.8 and 53.4; and the corresponding plasticity indexes, between 12.5 and 29.8. For the soft clay the liquid limits range between 36.5 and 55.0; and the plasticity indexes, between 12.3 and 28.4.

For the hard clay the water-plasticity ratio B was found to range between 40% and 100%; for the soft clay the range was from 150% to 240%.

Comparing the theoretical and actual decrease of water content and B-value with depth, the actual decrease is again found to be considerably larger than the theoretical decrease.

Such a clay must have been deposited at a water content very much above the liquid limit. Although it is not possible to reproduce in the laboratory the very slow growth of such a deposit, one can arrive at least at a lower limiting void ratio for the condition at which the material was deposited. For this purpose dispersed samples of soft Laurentian clay were permitted to flocculate. Irrespective of the chemical treatment, including one sample which was not treated at all, the deposits were found to have the same void ratio of about 5 after flocculation and sedimentation were completed. Consolidation tests were performed on these samples. The pressure versus void ratio curve of one of these tests (without chemical treatment) is shown in Fig. 38 as curve No. 4. The relationship determined from a consolidation test on the same clay in the undisturbed state is shown by curve No. 5. Thus, even with a void ratio of about 5.0 at the beginning of the test, the flocculated sample yielded an (e–p)-curve considerably below the curve for the undisturbed material. Probably the starting void ratio under the extremely slow natural growth of such a deposit is considerably greater than that obtained by rapid flocculation in the laboratory.

---

[80] Report on an Extensive Investigation of Slides in Eastern Canada, made by A. Casagrande to Irving B. Crosby, Cons. Geologist, January, 1931.

Curves Nos. 6 and 7 are speculations on the possible true virgin $(e\text{–}p)$-curve according to which this clay might have been consolidated by nature. There is some doubt about the meaning of the sharp initial curvature for curve No.5 after the preconsolidation pressure has been exceeded. Because of the imperfect fit of the sample in the consolidation ring, a lateral strain could be introduced which might result in a partial breakdown of the clay structure. However, three different tests on the same material gave almost identical results. One test was slow (70 days). If the shape of the curve beyond this

FIG. 38.—COMPARISON OF PRESSURE VERSUS VOID RATIO CURVES BY LOGARITHMIC PLOTTING

initial "disturbance" should continue about parallel to the natural virgin curve, one obtains curve No. 6, which could be assumed to begin at a void ratio of about 5. Taking into consideration the much greater drop of w_n-values and B-values with depth than is derived from the laboratory virgin (e–p)-branch, the natural virgin curve must be much steeper than either curve No. 5 or curve No. 6. Curve No. 7 is suggested as a curve which would explain this more rapid decrease of w_n and B with overburden pressure.

Ralph B. Peck, Jun. Am. Soc. C. E., is one of the few who have presented papers [81] containing complete water content and limit profiles. His investigations were made on Chicago clay. When considering only the clay that is unaffected by drying, his data[82] reveal, between depths of 25 and 45 ft, that the natural water content starts nearer the liquid limit at the upper elevation and approaches the plastic limit at the lower elevation. In both profiles the B-value drops from about 70% to about 30%, which is again a much greater drop than the theoretical drop of from about 70% to 60%, computed from laboratory virgin compression curves for similar clays.

Discussion of Variations of w_n, B, and p_p with Depth.—From the foregoing evidence, and similar observations at other localities, it is concluded that, for clays of the types described, the natural water content decreases with depth at a rate at least equal to that which would be expected from laboratory consolidation tests on undisturbed samples. In the foregoing examples the decrease in water content and water-plasticity ratio with depth is actually much greater than the theoretical decrease, which differs from Professor Terzaghi's views on this subject.[83,84] No explanation for this greater decrease is offered, except the tentative suggestion that the magnitude of the secondary compression, which develops over thousands of years, might increase in proportion to the overburden pressure. Thus, differences would result between laboratory and natural (e–p)-curves such as those shown by curve No. 5 and curve No. 7 in Fig. 38, which in turn would cause a greater decrease of water content with depth than the laboratory curve would indicate. However, it should be emphasized that very slow laboratory consolidation tests have so far shown rates of secondary compression along the virgin curve which are independent of pressure.

It is unlikely that the settlements of buildings are governed by (e–p)-curves as steep as curve No. 7 along which nature may have consolidated the clay over long periods. Rather, the (e–p)-curves, obtained from laboratory tests on good samples, seem to form a reliable basis for settlement analyses, provided that the preconsolidation pressure p_p can be determined with sufficient accuracy from laboratory tests, or geological evidence, or both. Without any knowledge of p_p one is forced to assume that the clay is consolidated only under the present overburden. The settlements so computed may be far too large.

The necessity of obtaining as accurate information as possible on the preconsolidation characteristics of clay deposits as a prerequisite for settlement analyses cannot be overemphasized, and the question of how to determine the true p_p is of major importance. Referring to the procedure for determining p_p from consolidation tests, Professor Terzaghi states that he has

[82] *Ibid.*, Figs. 19 and 20, pp. 1009 and 1110.

[83] "Undisturbed Clay Samples and Undisturbed Clays," by Karl Terzaghi, *Journal*, Boston Soc. of Civ. Engrs., July, 1941.

[84] Discussion by Karl Terzaghi of the paper, "Relation of Undisturbed Sampling to Laboratory Testing," by P. C. Rutledge, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1198.

> "* * * ceased to give any weight to the numerical results because both the published records and his own experience indicate that the difference between the computed and the real value for samples from the same drill hole may range between zero and several hundred per cent of the computed value. If the maximum preconsolidation load p_o exceeded the present overburden pressure p_1 by less than a few tons per square foot, the graphical method does not indicate whether p_o exceeded p_1 at all. In such instances, the writer relies entirely on geological evidence."

In the experience of the present writers it is just those cases, in which the maximum preconsolidation load exceeds the present load by a few tons per square foot, that require greater accuracy in analysis than is generally provided by geological evidence. The writers believe that this greater accuracy can be furnished by properly conducted consolidation tests on properly taken samples. As to geological evidence, Professor Terzaghi himself states: "* * * but, as a rule, geological evidence regarding the thickness of vanished strata leaves a wide margin for interpretation."

Furthermore, the thickness of vanished strata alone does not determine the preconsolidation pressure of clays. Except for very recent deposits, most clays have experienced one or more periods of drying which geological evidence will usually not reveal. Many apparent disagreements between p_p as determined from reliable tests and from geological evidence are due to preconsolidation of the clay by drying. Such differences can easily be "several hundred per cent of the computed value." In any event geological evidence would not inform the investigator of the degree and depth to which the clay was preconsolidated by drying. Where the telltale, hard, discolored crust has been eroded, only test results such as those shown in Fig. 33, and those obtained by any other testing methods that may be developed for this purpose, will reveal the existence and extent of consolidation due to drying.

If the large deviations between the true and computed p_p-values are caused by poor samples, or by poorly conducted consolidation tests, the procedure for determining p_p from the test results should not be blamed. Unfortunately, much unreliable information has been derived from tests made on badly distorted samples. Therefore, it is rather treacherous to rely on published data which are several years old, unless one has had an opportunity to check, scrupulously, all the many important details of sampling and testing which may cause erroneous results. It is regrettable that so much data obtained from soil testing of the past, including extensive material in the writers' files, must be eliminated as a source of reliable information because of the use of excessively distorted samples.

Further improvements or development of new methods for analyzing the pre-loading of clays from their stress-deformation characteristics are desirable. The loading history of a clay is a latent picture, somewhat like an undeveloped negative. The success of a settlement analysis depends largely on the ability to develop the picture.

Consolidation of clay by drying affects the magnitude of settlements of buildings in two ways: (1) Reduction in settlements compared to those of a clay of similar thickness that does not contain zones of dried clay; and (2) reinforcement of the clay stratum in the horizontal direction which assists in reducing settlements due to lateral deformation. The latter effect is similar to the reinforcement by layers of coarse-grained soil. Thick flood-plain deposits with their alternating layers of clay, sand, and silt, and with many of their clay layers well precompressed by drying, may show relatively small settlements as compared with the total thickness of clay in such deposits.

The idea of hydrostatic excess pressures in rock underlying clay was advanced by the senior author in 1936 as a tentative explanation for discrepancies in water-content distribution and consistency of so-called undisturbed samples of Boston clay. Observations have indicated that the water pressure in the rock underlying the clay corresponds to elevations above high tide.

It is difficult, if not impossible, to determine the intensity of the true water pressure in the rock underlying clay by water-level measurements in ordinary bore holes. Only by the use of special installations such as those devised for pore-water pressure measurements in clays can the pressure intensity be measured with sufficient accuracy.

Even these measurements must be viewed very critically because of the many technical difficulties involved in eliminating large errors. Not until perfectly reliable methods are developed, will it be possible to prove or disprove for a given site the existence of excess hydrostatic pressures in rock underlying clay.

Beneath extensive impervious clay deposits considerable excess hydrostatic pressure may be a natural and frequent phenomenon that may seriously affect the condition of consolidation of such clay deposits. Any relief in the excess hydrostatic pressure (as produced, for example, by wells) will result in consolidation of the clay under its own weight. Large changes in water pressure beneath clay deposits may result in spectacular settlements, such as those observed in the Santa Clara Valley in California.[85]

In this connection, the writers note with interest Mr. White's remarks, revealing a rather emphatic belief in the existence of such pressures.

Logarithmic Versus Semilogarithmic Plots of Pressure Versus Void Ratio Curves.—The remarks in the discussion by the Soil Mechanics Committee of the Los Angeles Section on the logarithmic plot of pressure versus void ratio curves touch a question which has been debated for a number of years.

In 1931 the senior author started plotting the (*e*–*p*)-curves of consolidation tests on undisturbed clay samples on semilogarithmic graph paper, chiefly because he found that it facilitated the estimation of preconsolidation pressures. As the results of tests on undisturbed samples on different clays accumulated, he noticed that the virgin compression branch plotted as a straight line for most of these clays. Only for clays with a natural void ratio considerably greater than 1.0, and with tests carried to large pressures, did he find that the virgin branch was more or less curved.

[85] "Ground-Water, Salt-Water Infiltrations, and Ground Surface Recession in Santa Clara Valley, California," by C. F. Tolman and J. F. Poland, *Transactions*, Am. Geophysical Union, 1940, Pt. I, pp. 23–35.

Shortly thereafter, investigators in Europe started independently to use the semilogarithmic plot as well as the logarithmic plot for presentation of $(e\text{–}p)$-curves.

Within the narrow working range of pressures which apply to the settlement analysis of a given structure, the virgin compression curves are practically straight lines, both on semilogarithmic and logarithmic plots. Then the choice may depend on whether the mathematical expression of a logarithmic function, or of a power function, is easier to use in a particular problem. The writers consider the logarithmic equation more easily handled in settlement analyses.[7]

The logarithmic plot has the advantage over the semilogarithmic plot in that it facilitates assembling on one diagram the results of soils with widely different compressibilities, as illustrated in Fig. 38. A number of sedimentary soils, which are curved on this plot, show straight-line virgin curves on a semilogarithmic plot. On the other hand, the clay from Mexico City, Mexico, which is not an ordinary clay but the result of chemical decomposition of volcanic ash, is a straight line on the logarithmic plot.

A minor disadvantage of the logarithmic plot is the necessity of using a much larger cycle size for the void-ratio scale than for the pressure scale to enable sufficiently accurate plotting. When plotting curves on symmetrical log paper, the $(e\text{–}p)$-curves of ordinary clays are so extremely flat that they would always give the impression of being straight lines.

Analysis of Time Curves from Consolidation Tests by Means of Semilogarithmic Plots.—Professor Krynine requested further information on this method. It consists of three parts: (1) Determination of the "theoretical zero," (2) determination of the boundary between primary and secondary compression, and (3) computation of the coefficient of permeability.

The necessity for finding a "theoretical zero" was realized by the senior author in 1928, after he discovered that the air content in soils invalidates the original procedure developed by Professor Terzaghi for analyzing time curves.[86] The method for finding the theoretical zero is based on the assumption that the upper half of the time curve is approximately a parabola, and consists of the following steps (on arithmetic and semilogarithmic plots): Choose an arbitrary point P_1 on the time curve, within the estimated first 50% consolidation. Divide the time, t_1, of this point by 4 and find the corresponding point P_2 on the curve. The difference in ordinates, Δ, of these two points is transferred above P_2, as illustrated in Fig. 37. This procedure is repeated for several points and the horizontal line passing through the average of the resulting locations is assumed to be the "theoretical zero coordinate."

With this modification, the senior author continued using the Terzaghi procedure, but in 1930 discovered very large discrepancies between the coefficient of permeability computed from the time curves and the directly measured values for undisturbed clays. After considerable experimentation with various types of plots, plotting the time on a log scale was found to permit visual differentiation between the primary and secondary compression. Also the intersection of the tangent to the inflection point and of the straight-line continuation of the secondary compression branch was found to correspond approximately to a theoretical consolidation of 100%.

---

[86] "Principles of Final Soil Classification," by K. Terzaghi, *Public Roads*, Vol. 8, 1927, p. 46.

Since both the theoretical zero point and the theoretical 100% point are subject to errors, the theoretical 50% point is considered least affected by these errors and was chosen instead of the 90% point in Professor Terzaghi's original procedure. Then for the time, t_{50}, corresponding to this theoretical 50% point, the coefficient of permeability can be computed from the following formula, based on the Terzaghi theory of consolidation:[87]

$$k = \frac{a_v \gamma_w H^2}{20 (1 + e_m) t_{50}} \qquad \text{(18)}$$

in which $a_v = \frac{p_2 - p_1}{e_1 - e_2}$ = coefficient of compressibility obtained from $(e\text{-}p)$-curve for increment; γ_w = unit weight of water; H = thickness of layer drained on both sides; $e_m = \frac{e_1 + e_2}{2}$ = average void ratio for the increment; and t_{50} = time for theoretical 50% consolidation, from Fig. 37.

Using the semilogarithmic plot for time curves, the writers have always been able to check, with satisfactory accuracy, the results of direct permeability tests with the k-values computed from the time curves, provided that the slope of the secondary compression branch was not so steep as to obliterate the bend in the curve indicating the transition from primary to secondary compression. This obliteration happens frequently in the case of peaty soils, but in inorganic clays only when very small load increments are used. The latter reaction is due to the fact that the slope of the secondary compression branch on a semilogarithmic plot is independent of the magnitude of the load increment; in other words, the greater the load increment, the sharper the line of demarcation between primary and secondary compression.

The use of the square root scale for the time curve, as introduced by D. W. Taylor, Assoc. M. Am. Soc. C. E., assists in determining the theoretical zero coordinate, but does not eliminate the difficulty of distinguishing between primary and secondary compression. The large discrepancies between the k-values computed from arithmetic or square root plots and the directly measured values are due to this difficulty.

In addition to more accurate computation of the coefficient of permeability, the semilogarithmic plot has an advantage over other plots in that the shape of the theoretical curve remains unchanged regardless of changes in the variables in Eq. 18. Once one is acquainted with the characteristic shape of the theoretical curve, a glance at an observed curve on a semilogarithmic plot will reveal numerous important details regarding the primary and secondary compression that cannot be seen in the other plots. For example, it will show whether the time allowed for consolidation has been sufficient, will furnish an estimate of the degree of accuracy of the computed k-values, or will show whether the secondary compression obliterates the primary compression to such an extent that it is not possible to compute k.

When performing consolidation tests one should always plot the time curves on semilogarithmic paper as consolidation progresses, to enable proper control of the test. Without such a precaution many tests are ruined by allowing insufficient time for consolidation.

[87] "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., 1943, p. 274.

STRESS DISTRIBUTION IN CLAY AND HOOKE'S LAW

The omission of stress diagrams showing the results of computations of stress distribution in the clay beneath the buildings was not intended to convey the impression, gained by several discussers, that the writers consider this subject of no importance. In the settlement analyses of the two buildings described, extensive computations were made to determine the stress distribution in the clay for different designs.

A number of papers in *Proceedings* in the past few years have described methods for making these computations. Since the results from all of these methods are sufficiently accurate for practical purposes, the choice of method is a matter of getting results with the minimum effort. For the analysis of building II, the junior author developed a set of influence charts, both for isotropic and anisotropic soils, which proved useful.[88, 89]

The distribution of stress in clay is probably more affected by anisotropic properties of such deposits than by deviations from Hooke's law. In the design of building II, various assumptions of anisotropy were made.[90]

Mr. Julian has presented a clear and scholarly review of those aspects of the theory of elasticity involved in the computation of stresses and settlements. His discussion reveals several interesting suggestions that should be of assistance to those desiring more information on this subject. Poisson's ratio of a given clay is not a constant quantity. For the purpose of computing the initial stress distribution clay is usually assumed to be a perfectly incompressible material.

The discussion of the Soil Mechanics Committee of the Los Angeles Section contains two conflicting statements on the question of the validity of Hooke's law. On the one hand, the committee proposes to expand the writers' statements on the limitations of the validity of Hooke's law to various types of soils, as follows: "Hooke's law does not apply to any soil." On the other hand, it proposes that shear stresses under rigid footings should be computed by means of the theory of elasticity, which presupposes the validity of Hooke's law. In addition, the shear stresses as computed for a uniform loading on a perfectly flexible footing are assumed to hold also for rigid footings. According to the theory of elasticity, infinite concentrations of shear stresses will occur under a rigid footing and a statement that the maximum shear stress will be equal to p/π is an unwarranted assumption. Either the material is almost perfectly elastic, in which case the maximum shear stress will be much greater than p/π; or the material is capable of making plastic readjustments where stresses are high, and then the maximum shear stress may be smaller than p/π. Fortunately, most soils have the property of distributing stresses from such parts where the shear strength is approached, to adjacent parts of the soil where shear stresses are moderate. This action can be compared with the manner in which steel adjusts stress concentrations which occur in almost every steel

[88] "Observations and Analysis of Building Settlements in Boston," by R. E. Fadum, a thesis submitted to the Faculty of the Graduate School of Eng., Harvard Univ., Cambridge, Mass., in May, 1941, in partial fulfilment of the requirements for the degree of Doctor of Science in Engineering (pp. 265–294).

[89] One of these influence charts is reproduced in "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., New York, N. Y., 1943, p. 485.

[90] "A Problem of Elasticity Suggested by a Problem in Soil Mechanics: Soft Material Reinforced by Numerous Strong Horizontal Sheets," by H. M. Westergaard, *Contributions to the Mechanics of Solids*, Stephen Timoshenko 60th Anniversary Volume, 1938.

structure. Just as the structural engineer relies on this property of steel, so must the foundation engineer rely on the capability of soils to release high stress concentrations.

PROPERTIES OF COHESIONLESS SOILS AFFECTING SETTLEMENTS AND BEARING CAPACITY

Have Simplified Rules a Place in Foundation Engineering?—In his contacts with the profession, the senior author has received frequent requests for a simplified presentation of the results of soil mechanics to serve as a guide to engineers who have neither the time nor the opportunity for a detailed study of soil mechanics. It cannot be denied that even today many architects and engineers are guided by the misleading concept that each soil has a constant bearing capacity, independent of the size and depth of the loaded area, and of the type of structure (see most handbooks and building codes). The designers are not entirely to blame if many building foundations are still designed by such completely inadequate, although age-old, rules.

Simplified formulations of the findings of soil mechanics have an important place in the design of building foundations and are practicable for coarse-grained soils. These formulations should convey at least qualitative information on the influence of possible variations in the design—for example, width, rigidity, and depth of loaded areas for the pertinent range in which such quantities ordinarily vary in building foundations. However, settlement analysis of buildings on soft soil does not as yet seem ready for such simplification.

In the first part of the paper a number of simplified formulations are presented concerning the behavior of loaded areas on cohesionless soils. These statements were included in an attempt to provide information which might be useful chiefly as a qualitative guide to the designer. Valuable comments were contributed on several of these statements.

(*a*) Discussers object to assuming zero pressure along the edge for rigid, loaded areas on the surface of cohesionless soil because no measurements by pressure cells have ever indicated zero pressure. It would require extremely small pressure cells to measure the pressure along the edge; but extrapolation from measurements made in the interior of such loaded areas has indicated practically zero pressures along the edge. In addition, from the strength characteristics of a cohesionless soil it follows logically that for the zero confining pressure at the edge the other stresses at this point must also disappear.

It was also objected that building footings are always extended to a certain depth below adjacent ground surface. However, there is a definite trend toward placing foundations for smaller buildings directly on the surface of a sand or gravel fill. This is also true of foundations for tanks. Therefore, a designer should know that zero edge pressure is a possible extreme limiting condition which he may have to consider.

In support of his claims that "There is no justification for the assumption that the intensity of pressure at the edge of a rigid area is zero," Mr. Feld refers to tests by Professor Converse.[18] These tests were not performed on the surface but at a depth of 4 ft. Furthermore, the soil was not cohesionless, but is described as "* * * a clay-loam, according to the classification of the

U. S. Bureau of Public Roads, and was made up of 29 per cent clay, 30 per cent silt, and 41 per cent sand."[91]

(*b*) In regard to pressure distribution on a rigid area supported at great depth, Mr. Feld states: "The uniformity of base pressure in pier foundations is the result of the rigidity of a deep footing rather than of the depth of the footing." Rigidity only insures uniform settlement. In the case of cohesionless materials, there is adequate proof that deformation does not occur in accordance with Hooke's law; therefore a uniform settlement does not insure a uniform base pressure at any depth.

The comments of Messrs. Terzaghi, Krynine, and Freeman on statement (*b*) are pertinent. Construction procedure, disturbance of the soil, and flexibility of the contact surface will result in considerable deviation from a uniform contact pressure. In most cases it is not possible to evaluate the influence of all these factors, and the assumption of a uniform contact pressure usually will be found to be on the safe side.

(*c*) Mr. Feld suggests rewording the statement on increase of ultimate bearing capacity with width of footing "* * * to the effect that the unit bearing is independent of the width of the loaded area." This is just the opposite of the writers' statement.

Professor Terzaghi states that the increase of ultimate bearing capacity approximately in direct proportion to the width of the loaded area "* * * does not apply to sands whose angle of internal friction decreases appreciably with increasing pressure." In the writers' experience, the angle of internal friction for a given sand can be assumed substantially constant in the range of pressure intensities encountered in normal building loads.

(*d*), (*e*), and (*f*) The ultimate bearing capacity, q_o, on the surface of a mass of cohesionless soil can be determined by load tests, keeping in mind that it increases approximately in direct proportion to the width of the area. By placing the same loaded area at increasing depths, h, the ultimate bearing capacity, q_h, will increase rapidly as compared with the value of q_o. This increase is due to a greater confinement of the soil underlying the area and to side friction. Thus,

$$q_h = q_o \left[1 + f(h)\right] \qquad \text{(19)}$$

in which the function of depth, $f(h)$, determines the increase with depth. The senior author has generally assumed a linear increase with depth, and in 1934 he was instrumental in introducing a modest linear increase into a proposal for a new building code for Boston.[92] More recently he has been led by observations in practice to consider a linear increase too conservative for shallow foundations.

For deep foundations the linear increase always applies, but in the writers' opinion the ultimate bearing capacity becomes so large that other factors than the ultimate bearing capacity control the design. For example, if a load test on an area 2 ft by 2 ft on the surface of a sand shows an ultimate bearing capacity of 4 tons per sq ft, the ultimate bearing capacity at a depth of only 4 ft would be more than 20 tons per sq ft; and, at a depth of 25 ft, more than 100 tons per sq ft, assuming a linear increase according to the conservative Eq. 22 which follows. Therefore, any simplified statement on the increase of ultimate bearing capacity with depth should apply primarily to comparatively shallow depths.

---

[91] *Civil Engineering*, April, 1933.

[92] "Proposed New Boston Building Code," by A. Casagrande, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., 1936, Vol. II, p. 311, paragraph (*d*).

The senior author considers Eq. 3 in its general form the best available expression for the pertinent shallow range. Professor Terzaghi considers it applicable for the range from zero depth to a depth equal to twice the width of a footing. He suggests that the linear formula, Eq. 4, represents the part of Eq. 3 within the range $1 < \frac{h}{R} < 4$. A better agreement with Eq. 3, including validity for the important range from the surface to a depth $h = R$, is afforded by the following equation in which the increase with depth is a parabolic function:

$$q_h = q_o \left[1 + \left(\frac{h}{R} \right)^{1.35} \right] \ldots\ldots (20)$$

In general form this equation may be written

$$q_h = q_o \left[1 + \left(\frac{h}{R} \right)^{m} \right] \ldots\ldots (21)$$

The exponent m depends largely on the soil properties and for shallow foundations varies from values larger than 1.0 to almost 2.0.

Most of the discussers expressed their belief in a linear increase of ultimate bearing capacity with depth, which is undoubtedly the simplest rational formulation. The question arises as to what form of linear increase would be suitable for safe application with a minimum of soil investigations. The following linear equation—

$$q_h = q_o \left(1 + \frac{h}{R} \right) \ldots\ldots (22)$$

—has the advantage that it is reliable for very shallow depths and that it can be safely used for any depth, since side friction is entirely neglected. For q_o one may use the results of load tests, or the following well-known formula,

$$q_o = R \, \gamma \tan^4 \left(45 + \frac{\phi}{2} \right) \ldots\ldots (23)$$

in which γ is the unit weight of the soil, buoyant below the ground-water surface. The angle of internal friction ϕ of a cohesionless soil can often be estimated from its general character and density.

When greater accuracy is desired for the usual working range from the surface to depths equal to several times the width of a footing, detailed soil investigations will be required. In this case, substitution of the increase along a parabolic curve by a straight line is not justified, and a more accurate formula, such as Professor Terzaghi's Eq. 3, in its general form, should be used.

For the purpose of a simplified statement the writers change formulation (*d*) in the paper to:

> The ultimate bearing capacity of a cohesionless soil increases with the depth of the loaded area beneath adjacent ground surface, approximately according to linear Eq. 22.

Mr. Freeman and the Soil Mechanics Committee of the Los Angeles Section disagree with the writers' statement that in the case of deep foundations on dense sand even the heaviest loading allowed by building codes is exceedingly conservative as far as the strength of the soil is concerned. They refer to the possibility of considerable differential settlement, which is not the issue in this statement. A footing may undergo objectionable settlement from a load which is still entirely safe as far as the strength of the soil is concerned. The occurrence of objectionable differential settlements does not imply that a safe load, as far as the strength of the soil is concerned, was exceeded.

(*g*) and (*h*) In discussing the validity of Hooke's law for cohesionless soils, Mr. Feld is apparently of the opinion that the Boussinesq formula does give satisfactory results for cohesionless soils—at least for small stresses. Mr. Julian states that there is a possibility that a cohesionless mass may have elastic properties when confined under high pressures. The writers agree with Mr. Julian, but believe that for most practical problems the assumption of Hooke's law for cohesionless materials leads to a distribution of soil reactions which are grossly in error.

(*i*) and (*j*) Messrs. Terzaghi and Freeman state that the decrease of settlements with depth may not apply to statement (*j*), depending largely on the effect of construction operations on the soil underlying the area to be loaded.

The writers agree fully with these qualifications. For example, when in an open excavation upward flow of water is allowed to develop, even the most compact and highly consolidated sand may change into a quick condition and become loose and highly compressible.

Within the usual working range of building footings (say, from depths of zero to 10 ft) the decrease of settlements for sand does apply and should be considered when designing such foundations.

In regard to the objections raised in the discussions, the writers propose the following modification of (*j*):

> With increasing depth of a loaded area, the settlement due to a given unit load will decrease appreciably only if the soil under the loaded area remains undisturbed. When disturbance is inevitable, the settlement may be assumed to be independent of depth.

The Liberty Mutual and New England Mutual Life Insurance Buildings

Building I, a foundation plan of which is shown in Fig. 17, is a ten-story tower-shaped office building having two setbacks. The plan area of the first two floors and basement is approximately 32,000 sq ft; the area of the third through sixth floors, approximately 20,000 sq ft; and the area of the seventh through tenth floors, approximately 10,000 sq ft. The dead load of this building, as computed from data furnished by the Turner Construction Company and based on actual quantities used in construction, is 39,500 tons. This dead load was approximately 5% less than the design dead load. The actual live load, as determined from an inspection of the building during which representative items of live load were weighed and unit intensities computed, is 1,500 tons. The effective weight of the soil removed to form a general basement, and in addition a sub-basement under the more heavily loaded ten-story section, is 35,000 tons. The net increase in load for the entire area is 6,000 tons.

Building II, a foundation plan of which is shown in Fig. 18(*a*), covers a plan area of approximately 66,000 sq ft. The section to the left of line EF and that to the right of GH are four-story sections. The area bounded by EGJI is occupied by a ten-story section; areas IMNK and OJLP, by two-story sections; and area FKLH, by a one-story section, with the exception of the center part, approximately 60 ft in length, which carries two stories. In the center of the building is an ornamental tower section approximately 40 ft square which rises 125 ft above the ten-story height. The dead load of this building, as determined from data furnished by the Turner Construction Company, and again based on actual quantities used in construction, is 110,000 tons. In this case 104,000 tons was the design dead load. The estimated actual live load is 6,000 tons. The effective weight of soil removed from this area is 127,000 tons. The estimated weight of two buildings which formerly occupied this site was 16,700 tons. The total weight removed from this area exceeds the weight applied in the form of the completed structure. This additional weight was removed to provide for dead-load increases and live-load increases in additions contemplated for the future and for which the foundations were designed.

The widths of all wall footings for building II were designed to provide for additional loads contemplated for the future. In many respects, however, the existing load distribution is more critical, and it is anticipated that, when the more lightly loaded sections are increased in story height, the differential settlements will diminish.

Both foundations were designed for dead loads plus actual live loads which were estimated as accurately as possible.

The thickness of the crust of hard and stiff clay was thoroughly explored during the construction of both buildings. For building I, the thickness was ascertained by making one hand-auger boring in the bottom of every caisson. The diameters of the caisson bells were proportioned in relation to the actual thickness of the crust. For building II numerous auger borings were made during the construction period to determine the variations in thickness of the crust. As a result of these explorations, it was decided during construction to raise the elevation of the base of the Berkeley Street exterior wall so as not to cut into the hard crust and unduly reduce its thickness. At this location the elevation of the base was slightly higher than at other places in the building area.

The design of the outside foundation walls for building II for horizontal forces was largely determined by the hydrostatic pressure. To this was added earth pressure at rest, buoyant below ground-water level. The temporary sheeting and bracing was designed on the basis of triaxial tests on undisturbed samples of the organic silt, making due allowance for a modest yield. Later the earth pressure was measured directly and found to check well with the design values.

Mr. Woolf takes exception to the specification for removing hard clay from under the sub-basement slabs to prevent them from bearing directly on hard material. This was necessary to assure that all loads would be transferred through the wall footings. Otherwise it would not have been possible to determine the soil reactions for which the slabs should be designed. Even if these pressures had been known, it would have been uneconomical to permit the slabs to carry the building load. If the crust of hard clay were not available, then a continuous mat would have been necessary, as emphasized by Mr. Freeman.

The main reasons for designing eccentric footings for the outside walls were: (1) Simplification of construction, and (2) more uniform distribution of the contact pressures on the base, considering water and earth pressure against the walls. The Building Department did not permit transmitting the earth pressure horizontally through the floor systems, thus necessitating transmitting these forces through the wall footings.

From the observed deflections, because he desired a comparison with the actual design, Mr. Woolf spot-checked the design of an interior wall for building II and computed the amount of reinforcing steel required to be 60 sq in. These walls were provided with 100 sq in. of steel in both the top and bottom.

Several discussers expressed a preference for the design of the foundation of building II over that of building I. When comparing these designs, the difference in the design of the superstructure should be kept in mind. The type of foundation designed for building II was made possible by the "columnless type" of building design.

Settlements.—The most recent settlement observations of buildings I and II were conducted after 6.5 and 3.8 years had elapsed, respectively, since installation of the observation points. The progress of the settlements is consistent with those reported in the paper. Table 2 summarizes the essential values.

TABLE 2.—SUPPLEMENTARY REPORT OF SETTLEMENT

Observation	Years elapsed	
(*a*) BUILDING I, LIBERTY MUTUAL INSURANCE COMPANY BUILDING		
Elapsed period, in years	4.3	6.5
Maximum settlement for point A93, Fig. 17 (curve I, Fig. 15(*b*))	1.85	2.04
Maximum differential settlement (curve I, Fig. 15(*c*))	1.02	1.18
(*b*) BUILDING II, NEW ENGLAND MUTUAL LIFE INSURANCE COMPANY BUILDING		
Elapsed period, in years	2.1	3.8
Maximum settlement (curve II, Fig. 15(*b*) and Fig. 23)	1.80	1.98
Settlement of point 9, Fig. 22	1.06	1.17
Maximum differential settlement (curve II, Fig. 15(*c*))	1.18	1.29

Referring to Fig. 20, Mr. Freeman concludes from the available observations that point 5, building II, might have risen considerably more than 2.9 in. before the rise was arrested by the weight of the concrete. The additional rise of point 5 which occurred in the period from October 12 to October 23, 1939, is estimated by the writers from a study of movements of points 4 and 6, Fig. 20, to be between 0.3 and 0.4 in. In this connection it should be emphasized that point 9 rose slightly after the foundation slabs and walls were installed at this location, due to an increase in hydrostatic pressure on the slab.

Mr. McAlpine inquires whether any of the adjacent buildings were adversely affected during or after construction. Great care was exercised in frequently observing elevations of observation points established on all structures in close proximity to the site of operations. No movements could be detected in any building surrounding the area. In this respect the soil conditions in Boston are more favorable than in some other cities where such deep excavations would invariably result in lateral flow of the soil and settlements of adjacent buildings.

The lack of symmetry in the settlement contours of the central area of building I, Fig. 17, is due to a nonuniform depth of excavation. The area enclosed by the heavy black line defines the sub-basement area. A depth of soil varying from the basement level to the sub-basement level was excavated from the area enclosed by the dot-dashed line on the Berkeley Street side of the sub-basement section. Had it been possible to excavate more soil at location A, the settlement pattern would probably have been symmetrical.

In reply to the requests by Messrs. Krynine and Burmister, for a comparison of computed and actual settlements, the following is quoted from a comprehensive investigation by the junior author:[93]

> "The analysis of data for six buildings located within the confines of Boston has suggested the following conclusions:
>
> "(1) Settlements due to consolidation, as computed from information disclosed by boring records, numerical data obtained from carefully performed consolidation tests of representative undisturbed samples, and stresses computed on the basis of the elastic theory, varied between values equal to and up to twice the magnitude of the observed settlements.
>
> "(2) Conservative estimates of the predicted differential settlements are obtained if, in computing the stresses by the elastic theory, the following simplifying assumptions are made: (*a*) The soil above the plane of loading and adjacent to the loaded area does not influence the distribution of the load below the plane of loading. (*b*) A structure is relatively flexible and does not redistribute the load as settlement occurs. It was generally observed that the ratio of the observed settlement to the computed settlement was low for points of large settlement and high for points of small settlement."

Recent investigations indicate that the excess of predicted settlements over actual settlements can be further decreased by considering more carefully the effect of preconsolidation of a substantial thickness of the clay stratum by drying.

CONTROL OF SETTLEMENTS BY COMBINING FLOTATION AND STIFFNESS

The interesting historical remarks by Professor Terzaghi on early applications of the principle of flotation to the design of foundations, and his discussion of the time lag between the inception of a new idea and its general acceptance, explain why the profession has so overlooked this method for almost one hundred years that it had to be rediscovered. However, he still leaves unanswered the question: Why is not more use made of this method in the design of modern buildings? The writers believe that the principle of flotation by itself is not sufficient to design satisfactory floating foundations for large buildings on soft ground. Just as ships require stiffness to withstand fluctuating support and variable loading, so must buildings floating on soft ground be designed to withstand nonuniform support and loading. In this connection, conclusion (5) of the paper deserves to be underscored. The problem of the design of such foundations is by no means solved in a completely satisfactory manner. Cooperation between architect and engineer should lead to novel and more practical designs in which full use is made of the superstructure in obtaining adequate stiffness.

---

[93] "Observations and Analysis of Building Settlements in Boston," by R. E. Fadum, a thesis submitted to the Faculty of the Graduate School of Eng., Harvard Univ., Cambridge, Mass., in May, 1941, in partial fulfilment of the requirements for the degree of Doctor of Science in Engineering (pp. 237 and 238).

If those structures are excepted in which functional requirements demand excavation at least equal to the weight of the structure, the method of flotation would probably be worth while only for very heavy structures, or structures with nonuniform load distribution.

Professor Zeevaert describes the application of an interesting and novel idea for compensating for the dishing effect by decreasing the depth of the excavation toward the edges of the building, thus assuring a more uniform stress distribution in the underlying soil. This method is theoretically sound and it would be worth while to have the details of this design made available to the profession. Professor Zeevaert expresses the opinion that heaving due to excavating in very soft clay is mainly caused by lateral plastic flow rather than by vertical expansion of the underlying clay. This is probably correct for Mexico City, although at the site of building II it was proved that the ground lost because of minor subsidence of the immediately adjacent street surface was of the same order of magnitude as the volume lost because of outward movement of the sheeting. The volume of the heave over the entire building area was of a much larger magnitude.

The writers concur with Professor Tschebotarioff's statement that, under different loading and soil conditions than those at building II, recompression following swelling may not be completed during the construction period.

Mr. Wilson suggests an interesting foundation design, which is intended more nearly to satisfy the requirement that the building load should be removed and applied simultaneously.

FLOATING FOUNDATIONS VERSUS DEEP FOUNDATIONS

The writers agree fully with Mr. White that deep foundations, which transfer load through soft clay on to hard underlying material, are preferable to floating foundations, when the cost of the former type is only a little higher than that of the latter. However, it was not the purpose of the paper to discuss foundations in which settlements are eliminated by carrying the loads on practically incompressible materials, but to present some applications of soil mechanics to the design of foundations which transmit load on to soft soil. The question as to when deep foundations should be selected was also beyond the scope of the paper.

For both buildings described, a pile or caisson foundation to rock would have been much more expensive than the floating foundation. For building II comparative cost studies were made for steel piles to rock, for caissons to rock, and for the floating foundation. These studies left no doubt that a deep foundation would be much more expensive than the floating foundation. A cost analysis of building II, after its completion, showed a unit cost for the substructure of $5.50 per ton load. This value may be compared with the actual cost of considerably more than twice this amount for a foundation to rock, consisting of open-end steel pipe piles, which was installed at a site in Greater Boston where similar subsoil conditions prevailed. When considering the value of the additional basement space provided by the floating foundation, the comparison is still more in favor of the floating foundation.

It was intimated in the discussions that only on the basis of detailed soil investigations, as conducted for these two buildings, would it be possible to design satisfactory floating foundations. However, most of these investigations served to analyze the settlements for foundations of a conventional type. These studies showed that such foundations would result in excessive differential settlements. Could it have been possible to decide beforehand on a floating type of foundation, most of these soil investigations would not have been necessary.

CONCLUDING REMARKS

In retrospect, several conflicting statements appear rather prominently in the discussions. On close scrutiny one finds that many of these conflicts are caused by a scarcity of reliable observations.

The designer is often confronted with the dilemma of whether to put more trust in observations whose accuracy he may have reason to doubt or in a theory which at best is a crude approximation. A theory can be modified to yield such a sufficiently wide range of results as may reasonably be expected to include the actual conditions. An observation is an empirical fact with which one cannot argue, unless one is thoroughly familiar with all the details.

Many observations from field and laboratory are subject to errors which render them valueless or actually misleading. For example, only a small percentage of measurements conducted with pressure cells can be considered reliable. The measurement of pore-water pressure in clays is assuming increasing importance, but it remains to be proved whether any of the existing measuring devices really give accurate results. Even the simplest field measurement (namely, the observation of settlements) has occasionally been subject to serious errors. Undisturbed samples of the same clay have been sent to different laboratories for shear strength tests. The results were so far apart that an objective observer must greatly wonder about the confidence with which such data were used in "accurate" stability computations. Therefore, let the frequently heard call for more observations and research on the behavior of earthworks and foundations be tempered by emphasis on quality rather than on quantity.

Acknowledgment.—The data from explorations of the clay deposits at the site of the Mystic Power Station are used with the permission of the Boston Edison Company and Jackson and Moreland, Engineers, for whom the writers made these investigations. The writers wish to thank R. P. Burden, of the Staff of the Harvard Graduate School of Engineering, for his assistance in the preparation of material and review of the text for this closure; and J. A. Delaney, of the staff of the Harvard Soil Mechanics Laboratory, for the performance of tests.

STRAINS, STRESSES, AND SHEAR IN ENGINEERING PROBLEMS

By Silas H. Woodard,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. M. Goodrich, Maurice P. van Buren, Joseph A. Wise, David B. Hall, Roberto Contini, I. Nelidov, Bernard L. Weiner, Richard W. Albrecht, Duff A. Abrams, C. A. P. Turner, Mark W. Huggins, A. A. Eremin, and Silas H. Woodard.

Synopsis

Formulas for strains and stresses on planes oblique to direction of principal stresses are developed in this paper. The thesis is offered that stresses are limited to tensile and compressive stresses; that shearing stress and shearing strength are misnomers; that shear is resisted by simple diagonal tensile and compressive stresses; that ruptures or failures occur when material is overstressed in tension; and that all failures in the field of engineering structures (except where plastic flow is classed as a failure) are tensile failures.

Fundamental Problems of Stress in Terms of Strain

Let Fig. 1 be the side elevation of a prism $A_1B_1C_1D_1$ of length H, and 1 unit by 1 unit in cross section, acted upon by force, p, parallel with the axis—that is, with the dimension H. During the application of the force, p, the prism changes from $A_1B_1C_1D_1$ to $A_2B_2C_2D_2$ or vice versa depending on whether p is compression or tension; the length of $\frac{H}{2}$ changes to the length $\left(\frac{H}{2} - h\right)$; the dimensions normal to the axis change to the length $(1 - 2\,b)$; the length of $a = \overline{OB_1}$ changes to the length $(d = \overline{OB_2})$.

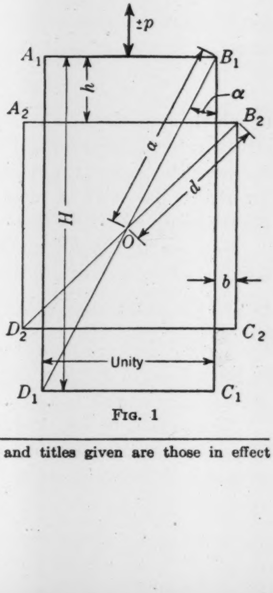

Fig. 1

Note.—Published in February, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr., New York, N. Y.

Let δ = strain in direction of $p = 2\frac{h}{H}$; δ_2 = (strain normal to direction of p) $= 2\frac{b}{1} = 2b$; δ_3 = (strain in direction of $\overline{\mathrm{OB}_1}$) $= \frac{a-d}{a} = 1 - \frac{d}{a}$; δ_n = (strain normal to direction of $\overline{\mathrm{OB}_1}$); $\mu = \frac{\delta_2}{\delta}$; and α = the angle between the direction of p and $\overline{\mathrm{OB}_1}$. Furthermore,

$$\sin\alpha = \frac{1}{2a} \qquad \text{(1a)}$$

$$\cot\alpha = \frac{H}{1} = H \qquad \text{(1b)}$$

$$a = \frac{1}{2\sin\alpha} \qquad \text{(1c)}$$

$$h = \frac{\delta\cot\alpha}{2} \qquad \text{(1d)}$$

and

$$d = \sqrt{\left(\frac{H}{2} - h\right)^2 + (\tfrac{1}{2} + b)^2} \qquad \text{(2a)}$$

Substituting values of H, h, and b, in Eq. 2a,

$$d = \tfrac{1}{2}\sqrt{(1-\delta)^2\cot^2\alpha + (1+\mu\,\delta)^2} \qquad \text{(2b)}$$

and

$$\delta_3 = 1 - \frac{d}{a} = 1 - \sin\alpha\sqrt{(1-\delta)^2\cot^2\alpha + (1+\mu\,\delta)^2} \qquad \text{(3)}$$

Simplifying Eq. 3,

$$\delta_3 = 1 - \sqrt{(1+\mu\,\delta)^2 + [(1-\delta)^2 - (1+\mu\,\delta)^2]\cos^2\alpha} \qquad \text{(4a)}$$

Usually the designer is interested in the stresses and strains normal to a given plane. From Eq. 4a it follows that

$$\delta_n = 1 - \sqrt{(1+\mu\,\delta)^2 + [(1-\delta)^2 - (1+\mu\,\delta)^2]\sin^2\alpha} \qquad \text{(4b)}$$

in which δ_n is the strain normal to any plane cutting a prism subject to axial stress in terms of the axial strain, Poisson's ratio μ and the sine of the angle α between the axis of the prism and the cutting plane. Eq. 4b is rather awkward for ready use, but it may be plotted into curves that are both useful and illuminating.

For practically all materials of construction the elastic limit is less than 0.004 E (E = modulus of elasticity) and working stresses are less than 0.001 E. It can be shown that the ratio, $\frac{\delta_n}{\delta}$, if computed by Eq. 4b, will be the same to the second decimal place for all values of δ less than 0.005. The uncertainties in the values of Poisson's ratio and the modulus of elasticity would vitiate any greater refinement.

The curves of Fig. 2 show, for various values of Poisson's ratio and for all angles, the strain normal to a plane that cuts a prism which is stressed axially, in terms of the strain in the direction of the axis as computed by Eq. 4b. The curves are for the following values of Poisson's ratio:

μ	Material
0.1	An approximate value for neat cement mortar
0.15	An approximate value for 1 : 3 mortar
0.2	An approximate value for ordinary concrete
0.25	An approximate value for stone
0.275	Value frequently used for steel
0.3	Another reported determination for special steel
0.33	Value generally used for copper
0.40	Value reported for lead

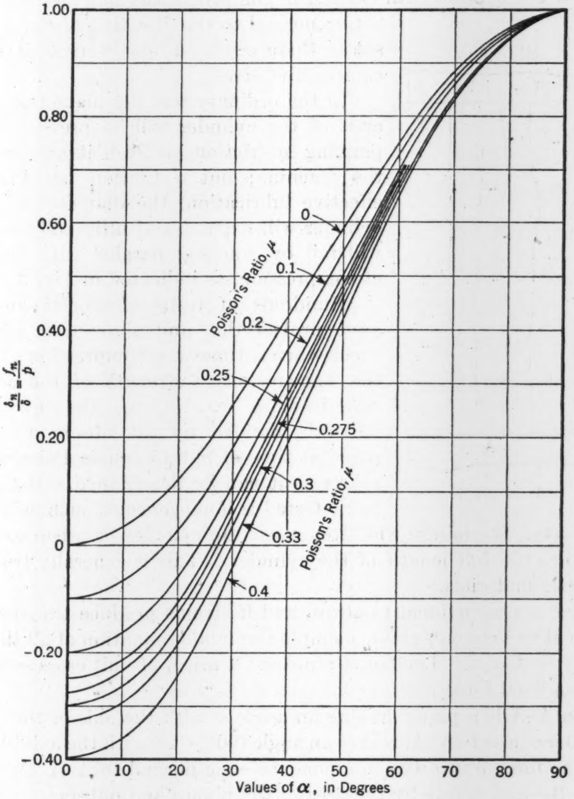

FIG. 2.—STRESS NORMAL TO A PLANE THAT CUTS A PRISM WHICH IS STRESSED AXIALLY

Interpolation may be made for other values of Poisson's ratio by simple proportion. If stress is proportional to strain, the curves of Fig. 2 can be used to read not only the strains normal to any plane cutting a prism in terms of axial strain of the prism but also the stresses, in terms of the principal axial stress, p.

In Fig. 2, the ordinates are marked to read both $\frac{\delta_n}{\delta}$ and $\frac{f_n}{p}$, in which f_n is the stress normal to the inclined plane. Of course, if p is tension, the ordinates above the x-axis will indicate tension and those below, compression. If p is compression, the ordinates above will indicate compression and those below will indicate tension.

Consider the case of a test specimen of a concrete cylinder or prism being subjected to axial pressure in a compression testing machine. By theory the diameter of the cylinder will expand in the proportion of Poisson's ratio and, acting normal to the direction of the compressive stress, there will be a tensile stress of μ times the compressive stress.

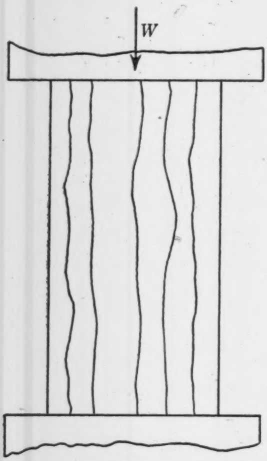

Fig. 3

In the ordinary test the diameters of the two ends of the cylinder will be prevented from expanding by friction between it and the heads of the machine; but if friction be eliminated by effective lubrication, the diameter of the entire cylinder will expand and ultimately the material will fail by cracking parallel with the direction of compression, as indicated in Fig. 3.

Hundreds of tests[2] of mortar and concrete have proved this and show that such failures occur when μ times the compression stress equals the known tensile strength of the concrete; or stated more exactly, f_t, the known tensile strength, divided by the observed compressive stress at time of failure equals Poisson's ratio as nearly as it can be determined. If the material being tested is homogeneous, such as 28-day neat cement mortar, the failure will often cause the cylinder or prism to break into small needles the full length of the cylinder. This is generally true of amorphous brittle materials.

If stress is proportional to strain and if strains produce transverse strains proportional to Poisson's ratio, a simple formula or equation of all the curves of Fig. 2 may be found. Let Fig. 4 represent a prism of unit cross sections acted upon by an axial force p.

Section A–A is a plane making an angle α with the axis of the prism; and plane B–B, normal to A–A, makes an angle $(90° - \alpha)$ with the axis of the prism. Resolve the force p into two components—one normal to A–A, the other normal to B–B—and divide by the area of the planes and obtain:

The normal force on unit area of plane A–A,

$$p_a = p \sin^2 \alpha \qquad (5a)$$

---

[2] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1092.

and the normal force on unit area of plane B–B,

$$p_b = p \cos^2 \alpha \ldots\ldots (5b)$$

Then by hypothesis the force p_a produces a strain normal to A–A, of

$$\delta_a = \frac{p_a}{E} = \frac{p \sin^2 \alpha}{E} \ldots\ldots (6a)$$

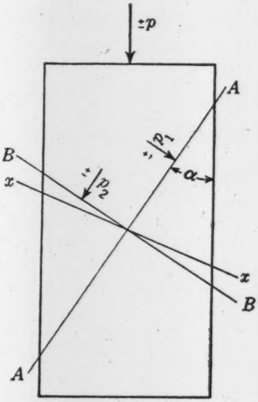

FIG. 4

but, force p_b produces a strain of opposite sign normal to A–A, of

$$\delta_b = -\frac{\mu\, p_b}{E} = -\frac{\mu\, p \cos^2 \alpha}{E} \ldots\ldots (6b)$$

The net strain normal to plane A–A is $\delta_a + \delta_b = \delta_n$. Then

$$\delta_n = \frac{p}{E}(\sin^2 \alpha - \mu \cos^2 \alpha)$$

$$= \frac{p}{E}[(1 + \mu) \sin^2 \alpha - \mu] \ldots (7)$$

and

$$f_n = E\, \delta_n = p\,[(1 + \mu) \sin^2 \alpha - \mu] \ldots (8a)$$

Another form for Eq. 8*a* is,

$$f_n = p\,[1 - (1 + \mu) \cos^2 \alpha] \ldots\ldots (8b)$$

In Eqs. 8*a* and 8*b*, p is the axial stress in a prism and f_n is the stress normal to a plane making an angle α with that axis. These formulas plot curves identical with those of Fig. 2. However, they can be derived directly from Eq. 4*b*. For example, write Eq. 4*b* in the form

$$\delta_n - 1 = -\sqrt{(1 + \mu\,\delta)^2 + [(1 - \delta)^2 - (1 + \mu\,\delta)^2] \sin^2 \alpha} \ldots\ldots (9a)$$

Squaring both sides of Eq. 9*a* and expanding the binomials:

$$\delta^2_n - 2\,\delta_n + 1 = 1 + 2\,\mu\,\delta + \mu^2\,\delta^2$$
$$+ (1 - 2\delta + \delta^2 - 1 - 2\,\mu\,\delta - \mu^2\,\delta^2) \sin^2 \alpha \ldots\ldots (9b)$$

But, δ^2_n, $\mu^2\,\delta^2$, and δ^2 are extremely small fractions, of the order of less than one millionth. Also they tend to cancel each other by opposite signs. If these can be dropped, Eq. 9*b* becomes

$$\frac{\delta_n}{\delta} = 1 - (1 + \mu) \cos^2 \alpha = \frac{f_n}{p} \ldots\ldots (10)$$

which is the same as Eq. 8*b*. The evidence indicates that Eq. 10 is applicable for all materials of construction up to the strains at which rupture occurs.

STRESS AND INTENSITY OF FORCE

It is common to conceive, and sometimes to define, stress as the normal component of the force known to be transferred across a unit area of cross section of a material. Referring to Fig. 4, the normal components of the force,

p, upon unit area of the planes A–A and B–B are

$$p_a = p \sin^2 \alpha \qquad (11a)$$

$$p_b = p \cos^2 \alpha \qquad (11b)$$

$$p_a + p_b = p \qquad (11c)$$

The normal stress f_a on plane A–A is given by Eq. 8*b*.

The difference between the intensity of normal force, p, and normal stress, f_a, on the plane is

$$p_a - f_a = \mu\, p \cos^2 \alpha \qquad (12)$$

It becomes important to distinguish between stress and force intensity. As used in this paper, stress f is defined as the magnitude of internal force normal to unit area which is accompanied by, and proportional to, strain in the same direction; or conversely, if the distance between two particles in homogeneous matter be changed, the proportional change is a measure of the stress on a unit area normal to the straight line between the particles. Force intensity p is defined as the sum of the normal components of all forces acting on unit area.

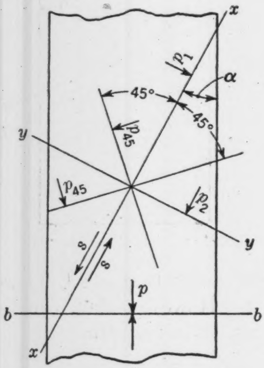

Fig. 5

Stress f may be greater than, equal to, or less than, force intensity p. This study indicates that f may be greater or less than p by a percentage not greater than Poisson's ratio, the variation being determined by the angles between the direction of principal stresses and the plane on which the stress or force intensity is acting.

Force intensity, although not a measure of stress, is a necessary and useful unit in problems of mechanics, and will be used in all appropriate equations of applied mechanics. Stress and force intensity are numerically the same when the stress is a single, maximum, principal stress, as, for example, p in Figs. 1 and 5. Furthermore, stress and force intensity are always numerically the same in any and every direction in a material for which Poisson's ratio is zero—but there is probably no such material.

The writer hereby enlists with the partisans of the Maximum Stress and Maximum Strain Theories of failure as opposed to the Maximum Shear Theory, the Maximum Distortion Energy Theory, and the Maximum Strain-Energy Theory. Although they are inseparable, the Maximum Strain Theory and Maximum Stress Theory are sometimes referred to as two independent theories.

SHEAR AND STRESS

It is common to use the terms shearing stress and shearing strength, but two logical deductions in the following study are that, (*a*) in materials strained by exterior forces including shearing forces, only two kinds of stresses are set up—compressive stresses and tensile stresses—and (*b*) shear is accompanied by and resisted by internal forces of tension and compression. In other words, there is no such thing as shearing stress or shearing strength as distinguished from compressive and tensile stresses and compressive and tensile strength.

However, the same deductions develop a rigid relation between shear and tensile and compressive stress so that shear and shearing intensities may be used to compute stresses.

Consider the simple case illustrated by Fig. 5 in which (x–x) is a plane making an angle α with the direction of a principal stress p (tension or compression). This stress is assumed to be the result of a single exterior force acting in the same direction. On plane (b–b) normal to the direction of the exterior force there is no shear and the stress is a maximum and is the same as the force intensity. Suppose the cross section (b–b) to have unit area, then the exterior force will also be p. The force intensity p_a normal to (x–x) will be as expressed by Eq. 5*a*, and the stress f_a will be as expressed by Eq. 8*b*. On plane (y–y) normal to (x–x), the force intensity p_b will be as expressed by Eq. 5*b*, and the stress f will be

$$f_b = p\,[1 - (1 + \mu)\sin^2] \qquad \text{(13a)}$$

The unit shear on either (x–x) or (y–y) will be

$$s = p \sin\alpha \cos\alpha \qquad \text{(13b)}$$

The force intensity normal to one of the planes making an angle of 45° with (x–x) and (y–y) will be (see Eq. 5*a*):

$$p_{45} = p \sin^2(\alpha + 45) = p\,(\tfrac{1}{2} + \sin\alpha\cos\alpha) \qquad \text{(14a)}$$

and normal to the other it will be

$$p_{-45} = p \sin^2(\alpha - 45) = p\,(\tfrac{1}{2} - \sin\alpha\cos\alpha) \qquad \text{(14b)}$$

Eqs. 14*a* and 14*b* represent two forces acting diagonally across the shear planes. The net effect of the components of p_{45} and p_{-45} parallel to the shear planes is their algebraic difference. These components on unit area of the shear planes are found by multiplying Eqs. 14*a* and 14*b* by $\sin^2 45°$, with the result that the net effect is found to be, $p \sin\alpha \cos\alpha$, which is the value of unit shear as given by Eq. 13*b*. In other words, the force intensities p_{45} and p_{-45} of Eqs. 14*a* and 14*b* are real forces and constitute a sufficient answer to the question of how shear is resisted without calling upon an imaginary and inexplicable thing called shearing stress.

If the shear per unit area on any pair of shear planes and the force intensity on each of the planes is known, then the direction and intensity of the maximum and minimum stresses can be computed (keeping in mind that the maximum and minimum stresses usually mean the maximum tensile and compressive stress or the minimum tensile and compressive stress and that the engineer is principally interested in finding the maximum stress to compare it with the known breaking stress). Let p_a = the force intensity on one shear plane; p_b = the force intensity on the other shear plane; s = the shear per unit area of the shear planes; μ = Poisson's ratio for the stressed material; and β and

$(90° - \beta)$ = the angles between the shear planes and any other plane such as (x–x), Fig. 4.

The stress $f_{(x-x)}$ on plane (x–x), then, is equal to

$$f_{(x-x)} = p_a [1 - (1 + \mu) \sin^2 \beta]$$
$$+ p_b [1 - (1 + \mu) \cos^2 \beta] \pm 2 s (1 + \mu) \sin \beta \cos \beta \ldots\ldots\ldots (15)$$

Eq. 15 follows if it be assumed that there are four principal stresses acting separately in the material under consideration, p_a and p_b acting normal to the shear planes and $+ p_c$ and $- p_c$ (numerically equal to s) acting at 45° to the shear planes. Then by determining the stress on the plane (x–x) making an angle β and $(\beta - 90°)$ with the shear-plane equation, by use of the preceding equations, Eq. 15 is obtained. To find the value of β which corresponds with the maximum value of f, place the first differential of f with respect to $\beta = 0$.

$$\frac{\delta f}{\delta \beta} = - 2 (1 + \mu) p_a \sin \beta \cos \beta + 2 (1 + \mu) p_b \sin \beta \cos \beta$$
$$- 2 (1 + \mu) s \sin^2 \beta + 2 (1 + \mu) s \cos^2 \beta = 0 \ldots\ldots\ldots\ldots (16)$$

from which

$$\sin^2 \beta = \tfrac{1}{2} \pm \tfrac{1}{2} \sqrt{\frac{(p_b - p_a)^2}{(p_b - p_a)^2 + 4 s^2}} \ldots\ldots\ldots\ldots\ldots (17)$$

Having found the values of β from Eq. 17, they may be substituted in Eq. 15 and the maximum and minimum stress, f, determined. As stress is numerically the same as force intensity p, if Poisson's ratio, μ, is zero, then

$$p = p_a \cos^2 \beta + p_b \sin^2 \beta \pm 2 s \sin \beta \cos \beta \ldots\ldots\ldots\ldots (18)$$

The two values of p (maximum and minimum force intensities) obtained from Eq. 18 are frequently called the principal stresses, but, according to the definition of stress in this paper, they are not equal to stress except in special cases; however, they are important and usable values. In the special case where $s^2 = p_a \times p_b$ (see Fig. 4), the maximum values of p and f are the same but not the minimum values.

When using Eqs. 15 and 17 it is usually more convenient to express p_a and p_b in terms of s. If $p_a = k_1 s$ and $p_b = k_2 s$,

$$\sin^2 \beta = \tfrac{1}{2} \pm \tfrac{1}{2} \sqrt{\frac{(k_2 - k_1)^2}{(k_2 - k_1)^2 + 4}} \ldots\ldots\ldots\ldots\ldots (19)$$

Consider some special examples of pairs of shear planes subject to unit shears equal to s and normal force intensities of p_a and p_b, respectively.

Example 1.—The case of pure shear on a given plane, such as at the neutral axis of a simple beam or on the cross section of a shaft subjected to torsion only. Here $p_a = 0$ and $p_b = 0$, and Eq. 17 becomes $\sin^2 \beta = \frac{1}{2}$, or $\beta = 45°$; $f = \pm (1 + \mu) s$, and $p = \pm s$. That is, there will be a unit stress of $+ (1 + \mu) s$ on one of the planes making an angle of 45° with the shear plane and a unit stress of $- (1 + \mu) s$ on the other; and on the same planes there will be a force intensity, $p = \pm s$.

Example 2.—In the case of a column or simple tension member under uniform axial stress equal to p; then $p_a = k\,s$; $p_b = \frac{s}{k}$; or $p_a\,p_b = s^2$. This will be true for every shear-plane section, and k will be equal to $\tan \alpha$, in which α is the angle between the shear plane and the axis of the member. Then, if β is the angle between a shear plane and the plane of maximum stress:

$$\sin^2 \beta = \tfrac{1}{2} \pm \tfrac{1}{2} \sqrt{\frac{k^2 - 1}{k^2 + 1}} = \cos^2 \alpha \ldots\ldots\ldots\ldots\ldots (20)$$

Eq. 20 is sometimes useful, and it furnishes confirmation of Eqs. 8*b*, 15, and 18.

Example 3.—The case of a combination of shear with one simple stress, such as a shaft under torsional unit shear s, and an axial tension or compression of, say, $p_b = k\,s$, then

$$\sin^2 \beta = \tfrac{1}{2} \pm \tfrac{1}{2} \sqrt{\frac{k^2}{k^2 + 4}} \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

TABLE 1.—MAXIMUM AND MINIMUM STRESSES (IN POUNDS PER SQUARE INCH) COMPUTED BY EQS. 15 AND 17
(Proof Tensile Strength 23,400 Lb per Sq In.)

Test No.	Applied shear	Applied tension	$\sin^2 \beta$	β	COMPUTED STRESS	
					Tensile	Compressive
3SA3	10,300	15,700	0.8031	63°–39′	22,500	10,900
3SA24	10,300	14,900	0.7927	62°–53′	21,910	11,110
3SA15	11,060	13,200	0.7510	60°– 0′	21,520	12,680
3SA18	11,060	13,800	0.7643	60°–57′	21,980	12,500
3SA21	11,060	14,300	0.7715	61°–26′	22,250	12,300
3SA4	12,860	11,700	0.7087	67°–26′	22,710	15,550
3SA20	12,860	14,100	0.7399	59°–21′	24,230	15,010
3SA10	12,720	10,300	0.6894	56°– 6′	21,750	15,700
3SA17	12,720	9,950	0.6823	55°–41′	21,500	15,750
3SA7	13,100	0	0.5000	45°– 0′	17,500	17,500

Table 1 shows the maximum and minimum stresses by Eqs. 15 and 17 for nine tests of combined torsion and tension on samples of aluminum, reported by Joseph Marin, Assoc. M. Am. Soc. C. E., and R. L. Stanley[3] in 1940.

The value of Poisson's ratio μ for the material tested is assumed to be 0.33. The proof tensile strength, 23,400 lb per sq in., was the mean of three tests which varied by 4.4%.

It will be seen that the computed maximum tensile stresses agree with the proof tensile strength as closely as the test results in each group agree with each other. Unfortunately, there were no compression tests to determine the proof compressive strength. The single pure shear test (torsion only) yielded at a unit shear of 13,100 lb per sq in., for which the stress computed by Eqs. 15 and 17 would be 17,500 lb per sq in. compression on one diagonal and 17,500 lb per sq in. tension on the other. It may also be noted that the stress-strain curves in the determination of the "proof strength" indicate the yield point to be about 17,500 lb per sq in. Possibly the compressive proof strength would be approximately 17,500 lb per sq in.

---

[3] "Failure of Aluminum Subjected to Combined Stresses," by Joseph Marin and R. L. Stanley, *Supplement, The Welding Journal*, February, 1940, Vol. 19, pp. 74s–80s.

Conclusions

It is obvious that—

(*a*) Poisson's ratio must be used in the more accurate computations of stresses; and

(*b*) Shear intensity is not a stress but is always accompanied and resisted by diagonal tensile or compressive stresses or both.

Other conclusions may be deduced from the formulas developed herein, therefore, such as,

(*c*) If shear exists on a plane section at a given point, then the maximum or principal stress at that point is not normal to the plane. This fact is frequently overlooked;

(*d*) If the principal stress is known at any point, the stresses in all other directions may be found;

(*e*) Conversely, if the shearing and force intensities on a pair of shear planes at any point be known, the directions and magnitude of the maximum or principal stresses may be found;

(*f*) The stresses in all other directions may be computed either from the principal stresses or direct from the shear and force intensities.

Both from the formulas herein and from practical observation, it is concluded that ruptures of material under compression are tensile failures; also, that tests to determine compressive strength as usually made, especially those on mortars and concrete, give incorrect results and indicate too high strength because of the resisting effect of friction on the ends. If this is true, the testing methods should be revised to eliminate friction which can be done easily, or a correction factor should be determined to apply to the results of tests as now made.

DISCUSSION

C. M. Goodrich,[4] M. Am. Soc. C. E.—The newer theories of Sandel and Schleicher[5] are in better agreement with tests than were the older theories. Mr. Sandel considers the change of length in the long diagonal in a cubic element to be the measure of allowable distortion and equates this to the distortion under a single axial load to obtain his criterion of safety. Mr. Schleicher[6] follows the same argument, "Gestaltänderung" (or "Change of Shape"). Their results differ (but not greatly; see Table 2) possibly because of a difference in the value of Poisson's ratio.

TABLE 2.—Comparison of Stress Theories[a]

For:	Sandel	Schleicher
σ_x, σ_y, τ	$\sigma = \sqrt{\sigma^2_x + \sigma^2_y - 0.865\,\sigma_x\,\sigma_y + 2.865\,\tau^2}$	$\sigma = \sqrt{\sigma^2_x + \sigma^2_y - \sigma_x\,\sigma_y + 3\,\tau^2}$
σ_x, σ_y	$\sigma = \sqrt{\sigma^2_x + \sigma^2_y - 0.865\,\sigma_x\,\sigma_y}$	$\sigma = \sqrt{\sigma^2_x + \sigma^2_y - \sigma_x\,\sigma_y}$
σ_x, τ	$\sigma = \sqrt{\sigma^2_x + 2.865\,\tau^2}$	$\sigma = \sqrt{\sigma^2_x + 3\,\tau^2}$
τ	$\sigma = 1.69\,\tau$	$\sigma = \sqrt{3}\,\tau$

[a] σ_x is the unit stress in one direction, σ_y is the unit stress at right angles to σ_x, and τ is the shear.

To illustrate the procedure, consider the case of pure shear in comparison with tension. Under a single tensile load the distortion $\epsilon_1 = \frac{\sigma}{E}$ and $\epsilon_2 = \epsilon_3 = -\frac{\mu\,\sigma}{E}$; and for the diagonal, $\epsilon = \sqrt{\epsilon^2_1 + \epsilon^2_2 + \epsilon^2_3} = \frac{1}{E}\sqrt{\sigma^2 + 2\,\mu^2\,\sigma^2}$. If $\mu = 0.3$,

$$\epsilon = 1.086\,\frac{\sigma}{E} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

In a case of shear only (see Fig. 6), since the cube of investigation is infinitely small, a cube of the same size at 45° with the old cube is its equivalent. In this new cube each unit axial stress equals the old unit shear stress. The change of length of the diagonal in the square is $\epsilon = \sqrt{\epsilon^2_1 + \epsilon^2_2}$. Now $\epsilon_1 = \frac{\tau}{E}(1 + \mu)$, and $\epsilon_2 = -\frac{\tau}{E}(1 + \mu)$, whereas $\epsilon_3 = 0$.

[5] *Stahlbaukalender*, 1937, p. 24.

[6] *Bauingenieur*, 1928, p. 253.

Accordingly, the distortion of the long diagonal of the square (which, since $\epsilon_3 = 0$, is also the distortion of the long diagonal of the cube) is

$$\epsilon = \frac{\tau}{E} \sqrt{2\,(1 + 2\,\mu + \mu^2)}; \text{ or, if } \mu = 0.3:$$

$$\epsilon = 1.8386 \frac{\tau}{E} \qquad (23)$$

Equating formulas 22 and 23

$$\sigma = 1.69\,\tau \qquad (24)$$

When the bearing surfaces testing a stone cube are well greased,[7] the characteristic pyramids shown in Fig. 7 no longer appear, and the pressure required to break the cube drops to one half or less of what it is where friction helps the specimen.

The stresses indicated in Table 2 are to be taken as equivalent stresses. Consider a steel cube under compression in the vertical direction; its sides bulge and then flow when the elastic limit is exceeded. The writer was taught, and still believes, that the sum of all forces in any direction should equal zero.

MAURICE P. VAN BUREN,[8] ASSOC. M. AM. SOC. C. E.—Interesting adventures in mathematics can be developed from false premises. In referring to a concrete cylinder subjected to axial pressure in a compression testing machine (see heading, "Fundamental Problems of Stress in Terms of Strain"), the author states

> "* * * By theory the diameter of the cylinder will expand in the proportion of Poisson's ratio and, acting normal to the direction of the compressive stress, there will be a tensile stress of μ times the compressive stress."

From this postulate, various unusual conclusions are derived. One of these is Eq. 12 which expresses a difference between the intensity of normal force and normal stress on a plane.

In the generally accepted theory, the effect of an axial force on the dimensions of a body resembles temperature change in that, for given conditions, there is a natural size and shape which the body tends to assume. Lateral expansion or contraction from such causes produces stress only if prevented, in which case the stress will be of the same kind as the axial force. This is obvious from Fig. 1, where, by the principles of equilibrium, there can be no resultant lateral force unless external compression forces are applied to the sides of the piece. However, in short thick cylinders, the inner layers may be restrained by the resistance of less heavily loaded outer fibers, causing a balance of equal and opposite internal circumferential forces. The amount of these forces will bear a definite relation to Poisson's ratio and may explain lateral tension failures under compressive tests of certain brittle materials already subject to high initial cohesive stresses.

If derived from correct concepts, formulas expressing the stresses and strains involved in lateral expansion and contraction will follow accepted theory and can be found in any standard handbook of mechanics. Such deformations naturally affect the behavior of all materials, to a greater or less extent, depending on particular characteristics, shape, loading, and initial stress. In any event, in themselves, the deformations prove nothing regarding the fundamental causes of failure in general.

[8] Cons. Engr. (J. Di Stasio & Co.), New York, N. Y.

JOSEPH A. WISE,[9] M. AM. SOC. C. E.—Some interesting ideas are presented in this paper, but unfortunately some fundamental errors are involved that vitiate most of the conclusions. The first of these errors is the tacit assumption that in an elastic solid there must be a stress proportionate to, and in the direction of, every strain. Consider the illustration, used in the paper, of a concrete cylinder with a uniformly distributed compressive force applied axially. There is a lateral strain of μ times the axial strain (μ being Poisson's ratio), but it does not follow that there is any lateral stress. Incidentally the paper limits its discussion to co-planar states of stress, although, for a thorough presentation, a possible triaxial state of stress must be considered.

Fig. 8 shows a concrete cylinder with a compressive load applied in the direction of the z-axis, so that the unit force or unit stress is σ_z. Assume complete freedom of lateral displacement on the end surfaces in order to avoid unnecessary complexities introduced by lateral restraint. The state of stress will be assumed homogeneous; that is, all elements will have the same stress, σ_z. Take an element at the outer surface, as shown. On inspection $\sigma_x = 0$, since there is no external force applied in the x-direction. Similarly, σ_y must be zero, otherwise one could not satisfy the equation of static equilibrium, $\sum y = 0$. From tests it is known, however, that transverse strains occur; and therefore strains occur, but no stresses, in the x-direction and y-direction. It would do no good to assume any hypothetical arrangement of tensions on the outer surface and compressions in the core, as, when the conditions for static equilibrium have been met, the net total strain in the x-direction and in the y-direction would be zero (due to any such set of forces) and would not account for lateral strain. The same error renders Eqs. 8*a* and 8*b* of the paper incorrect. Then in Eq. 8*a*, f_n is not equal to $E \delta_n$, and likewise Eq. 8*b* is incorrect since the stress is not necessarily equal to E times the strain. This error is implicit in the complex definition of stress used in the paper and invalidates most of the subsequent work. In defining stress as normal force per unit area which is accompanied by, and is proportional to,

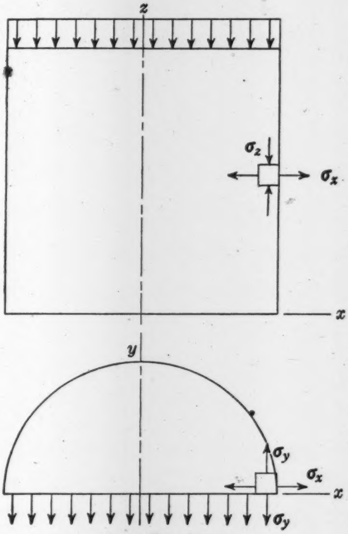

FIG. 8

---

[9] Lt. Comdr. (CEC), U. S. N. R., Public Works Office, 3d Naval Dist., New York, N. Y.

strain in the same direction, an unnecessary and unusual limitation is placed upon the concept of "stress" and, by implication, this leads to the erroneous concept that every strain must have a stress proportional to it and in the same direction.

Definitions are limitations imposed on words so that speech and writing will convey more accurate concepts. In setting up his new definitions of stress, the author does not convey more accurate concepts thereby and no longer is using the language that is basic to the various theories of failure enumerated. The customary definition of stress, heretofore used, is that stress is force per unit area within a solid. This is amplified by defining normal stress (tension or compression) as force per unit area acting perpendicularly to the area in question, whereas shearing stress is force per unit area acting parallel to and on the surface of this area. Since most of the references to the subject under discussion used these definitions, the writer will use them also. It may be pointed out that some of the errors inherent in the paper arise from the definitions which implicitly contain false assumptions. This is the reason for rejecting the proposed definitions and adhering to the customary ones. Based on these generally accepted definitions, the value of the principal stresses for Table 1 of the paper have been recomputed in Table 3.

In stating that the Maximum Stress Theory and the Maximum Strain Theory are inseparable, the author fosters a misconception that stems from the proposed definitions. The Maximum Stress Theory is the naive one which states that materials rupture when a definite maximum normal stress exists. This has been shown to be untenable, and Table 3 shows how far from true it is. The tensile strength of the aluminum was 23,400 lb per sq in.; yet all the specimens failed at lower tensile stresses. In test 3SA7, although the tensile stress was only 56% of the ultimate tensile strength, rupture occurred.

The Maximum Strain Theory, which states that materials fail when a maximum elongational strain occurs, is the theory usually considered the explanation for the failure of brittle materials such as concrete. The interpretation that the strain must be due to a stress in the same direction is incorrect, as has been shown. The proper interpretation of tests on concrete mentioned by the author, according to this theory, is that in pure tension specimens the elongational strain is equal to $\frac{\sigma}{E}$, of course, and failure is ascribed to excessive

TABLE 3.—RECOMPUTATION OF MAXIMUM AND MINIMUM STRESSES IN TABLE 1

Test No.	Applied shear	Applied tension	Maximum tension	Maximum compression	Maximum shear
3SA3	10,300	15,700	20,800	5,100	12,950
3SA24	10,300	14,900	20,160	5,262	12,712
3SA15	11,060	13,200	19,433	6,233	12,833
3SA18	11,060	13,800	19,890	6,090	12,990
3SA21	11,060	14,300	20,275	5,975	13,125
3SA4	12,860	11,700	19,978	8,278	14,128
3SA20	12,860	14,100	21,716	7,616	14,666
3SA10	12,720	10,300	18,873	8,573	13,723
3SA17	12,720	9,950	18,632	8,682	13,657
3SA7	13,100	0	13,100	13,100	13,100

strain, not excessive stress. In a compression specimen, when the lateral strain reaches this value, failure occurs although there is no lateral stress present.

The Maximum Shear Theory states that materials fail when the shearing stresses reach the maximum shearing strength of the material. This is in much better agreement with test results on ductile materials than the two preceding theories, as may be seen from Table 3. The shearing strength should be 50% of the ultimate tensile strength, or 11,700 lb per sq in. This theory has been modified by Mohr[10] to make the shearing strength a function of the maximum tensile stress and is in somewhat better agreement with some test results than the unmodified Maximum Shear Theory. Mohr's theory can be best illustrated by means of Mohr's circle of stress as in Fig. 9.

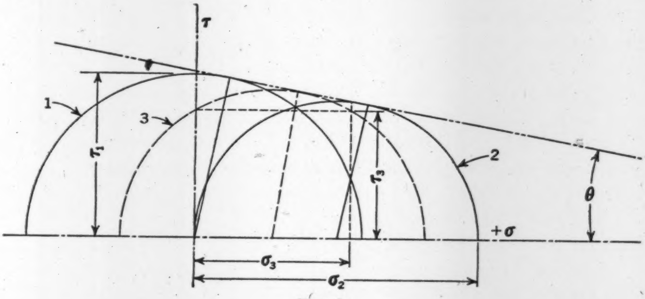

FIG. 9

Here τ_1 in circle 1 is the maximum shearing strength in pure shear, σ_2 in circle 2 is the maximum tensile strength in pure tension, and σ_3, τ_3 are the tensile and shearing stresses in any combined shear and tension. Mohr's theory states that these circles all touch a common envelope, which approximates a straight line making an angle θ (approximately 15°) with the horizontal. Circles of stress and circles of strain[11] are useful graphical aids in presenting the relationships between stresses and strains.

The Maximum Strain Energy Theory states that materials rupture when the strain energy introduced exceeds a maximum value. The Maximum Distortion Energy Theory states that materials rupture when the distortion energy exceeds a limiting value. Distortion energy is defined as total strain energy minus volume-change energy. This last theory was shown to be in better agreement with test results than the others for the tests referred to in the paper[12] from which Table 1 was taken.

The failure or disruption of materials is a subject that will probably require much further research before engineers can select the best theory of failure, and several theories may be valid, each for its own realm and for certain types of materials. Pending such research, present theories should be regarded as purely tentative and expedient approximations—using the Maximum Strain Theory for brittle materials and either the Mohr Maximum Shear Theory or the Maximum Distortion Energy Theory for ductile materials.

[12] "Failure of Aluminum Subjected to Combined Stresses," by Joseph Marin and R. L. Stanley, *Supplement, The Welding Journal*, February, 1940, Vol. 19, pp. 74s–80s.

David B. Hall,[13] Assoc. M. Am. Soc. C. E.—Before discussing any of the conclusions of this paper, the writer finds it necessary to take exception to the terminology used. Throughout the literature of elasticity, plasticity, and strength of materials, the term "stress" is used universally to designate the forces that must act across any plane in a body to maintain equilibrium. Since matter is not continuous but consists of thinly dispersed particles, it is understood, of course, that stress in the foregoing sense is a statistical, or average quantity, much the same as gas pressure, which, although actually consisting of a bombardment by gas molecules, can be, and is, measured in pounds per square inch. There is no reason why the author should abandon the term "stress" and substitute "intensity of force." The interatomic phenomena in a stressed body are no doubt very complicated. The author has elected to reserve the term "stress" for some phenomenon, apparently of this kind, although he has offered no explanation of its nature further than that stress is something that is proportional to strain. As so defined, stress serves no purpose which could not be served equally well by attributing any phenomenon related to strain directly to strain itself. That the author's transposition of accepted terms is confusing is well illustrated by his own statement in his discussion of failure theories: "Although they are inseparable, the Maximum Strain Theory and Maximum Stress Theory are sometimes referred to as two independent theories." The Maximum Stress Theory refers to stress as ordinarily defined and is entirely unrelated to the Maximum Strain Theory. Throughout the remainder of this discussion the writer proposes to use the words "stress" and "strain" in their usual and accepted meanings.

The paper presents two conclusions which warrant close examination: (1) There is no such thing as shearing stress or shearing strength; and (2) the failure of materials under combined stress is to be predicted by the Maximum Strain Theory.

1. The assertion that there is no such thing as shearing stress or shearing strength easily could wander off into the fields of metaphysics, but a few definite statements can be made with comparative safety. First, the concept of shear is clear enough: If the resultant stress acting across a plane within a body is inclined to that plane, it can be resolved into a normal component called normal stress and a tangential component called shearing stress. Second, failure may occur along a plane (*a*) if the resistance of the material to rupture is less than the normal stress or (*b*) if the resistance of the material to sliding or plastic flow is less than the shearing stress.

The author's proof of the nonexistence of shear is found to proceed something like this: If shearing stress exists on one plane, then there must be normal stresses on planes inclined at 45° to this plane. Therefore (?) the normal stresses on these inclined planes are real and resist external loads, whereas the shearing stress on the plane first considered is redundant and unnecessary.

---

[13] Designer, Howard, Needles, Tammen & Bergendoff, New York, N. Y.

The fallacy of this argument is not difficult to discover. The fundamental requirement of equilibrium of stress at a point is that the stresses on the various faces of any small figure surrounding the point shall be in equilibrium. The author has failed to recognize this requirement. In effect, instead of declaring that the stress on one face of a small triangular prism must balance the stresses on the other two (the ends being free of stress), he has stated that stress on one face may be replaced by stresses on the other two.

TABLE 4.—COMPARISON OF FAILURE THEORIES FOR ALUMINUM SHAFTS

(In Pounds per Square Inch)

Test No.	Reported Stress		Principal Stresses			Ratio $\frac{p_0}{23{,}400}$

3SA7	13,100	0	13,100	0	−13,100	0.56	0.75	1.12	0.97

2. The failure of materials under combined stress is to be predicted by the Maximum Strain Theory. Table 4 has been prepared to compare the failure stresses reported in Table 1, for some aluminum shafts, with the failure stresses predicted by four common theories. This has been done by calculating a simple axial tension assumed to be equivalent to the combined stress reported and by comparing it with the known tensile strength of 23,400 lb per sq in. The three principal stresses were first obtained:

$$p_2 = 0 \qquad (25a)$$

$$\left.\begin{matrix} p_1 \\ p_3 \end{matrix}\right\} = \frac{1}{2}\,p \pm \sqrt{\left(\frac{p}{2}\right)^2 + s^2} \qquad (25b)$$

in which p_1, p_2, p_3 = principal stresses, in descending order of magnitude, p = reported tensile stress, and s = reported shear stress. The equivalent simple tension, p_0, was then obtained in terms of p_1, p_2, and p_3, according to the rules for each of the four theories: For Maximum Stress Theory—

$$p_0 = p_1 \qquad (26a)$$

for Maximum Strain Theory—

$$p_0 = p_1 - \mu\,(p_2 + p_3) \qquad (26b)$$

for Maximum Shear Theory—

$$p_0 = (p_1 - p_3) \qquad (26c)$$

and, for Octahedral Shear Theory—

$$p_0 = \sqrt{\frac{(p_1 - p_2)^2 + (p_2 - p_3)^2 + (p_1 - p_3)^2}{2}} \quad \ldots\ldots\ldots (26d)$$

As has been observed generally for ductile materials, the octahedral shear formula gave conspicuously more accurate results than any of the others. Also, it will be noted that the Maximum Strain Theory erred consistently on the side of danger.

Tests on Concrete Cylinders.—In further support of the Maximum Strain Theory the paper cites compression tests performed on concrete cylinders and prisms with lubricated ends. Significant results of the tests were: The specimens failed by splitting; failure occurred under a stress producing lateral extension approximately equal to the elongation at which specimens fail in tension; and failure occurred at substantially lower stresses than in specimens tested in the ordinary manner. The explanation offered by the author to account for the difference between the behavior of lubricated and unlubricated specimens is that the latter are prevented, by end friction, from expanding laterally and thereby are prevented from failing. The answer may not be as simple as this. In particular, the lateral restraint at the ends is a more or less local effect. Therefore, according to the author's hypothesis, (*a*) failure of unlubricated specimens should originate at the middle, where the strengthening effect is least, instead of at the ends as was observed, and (*b*) the strength of restrained specimens should approach that of lubricated specimens as the length is increased.

A condensed summary of the results of the tests is given in Table 5. The anticipated convergence of strength values for increase of length seems to be indicated by the table, although the results are erratic, and the mortar cylinders vary in exactly the opposite manner. Table 5 also shows so great a difference between strengths of plain and lubricated specimens as to suggest that some other factor may have been at work to reduce the strength of the lubricated specimens. The specimens were lubricated by sheets of blotting paper saturated with grease. Conceivably this method may have had two possible effects: There may have been a hydraulic pressure gradient across the ends,

TABLE 5.—EFFECT OF LENGTH AND END CONDITIONS ON STRENGTH OF MORTAR COMPRESSION SPECIMENS[2]

Length diameter	Compression Strength for Plain Ends / Compression Strength for Greased Ends				
	1 : 3 Mortar		Neat Cement		Average all specimens
	2-in. diameter cylinder	4-in. by 4-in. prism	2-in. diameter cylinder	4-in. by 4-in. prism	
1	1.11	1.55	1.83	1.95	1.61
1.5	1.20	1.75	1.80	1.56	1.58
2	....	1.40	1.78	1.28	1.49
3	1.44	....	....	....	1.44
4	1.40	1.05	1.20	1.12	1.19

resulting in a maximum pressure exceeding the average; and the lubricant may have hastened failure by transmitting hydraulic pressure to all cracks as fast as they formed. These explanations are only speculative, but they do serve to emphasize the precariousness of a combined stress theory based on a comparison of greased and dry concrete columns, instead of on tests of the kind exemplified by Tables 1 and 4.

The evidence presented in support of the maximum strain failure theory thus sums up to two items:

I. Combined shear and tension tests on aluminum shafts which clearly show the superiority of another theory; and

II. A comparison of cement mortar columns with and without greased ends which, at best, points toward the Maximum Strain Theory as a plausible possibility.

The paper concludes with the suggestion that compression tests of concrete should be made on greased specimens, or a factor should be introduced to give equivalent values. Since all concrete column tests invariably include the making and testing of control specimens to measure concrete strength, it would appear that all necessary factors are included automatically.

Roberto Contini,[14] Jun. Am. Soc. C. E.—Except for conclusions (*a*) and (*b*), the "Conclusions" of this paper are altogether correct. However, they are among the most elementary results of the Theory of Elasticity and have been known for decades. Moreover, the general approach is not correct.

For example, the definition of stress as given by the author does not have any physical meaning. In fact the stress, f, defined as (see heading, "Stress and Intensity of Force") "* * * the magnitude of internal force normal to unit area which is accompanied by, and proportional to, strain in the same direction * * *," is merely the strain in any direction multiplied by Young's modulus E. It is a quantity proportional to strain by definition and not because of any physical fact and, except for very particular cases, does not represent any actual force per unit area existing in the material.

The author states that it is common to conceive, and sometimes to define, stress as the normal component of the force known to be transferred across a unit area of cross section of a material. In fact, this is the definition of normal stress as used in the Theory of Elasticity and seems to be the only possible definition of normal stress.

A misinterpretation of Hooke's law that "strain is proportional to stress" seems to have occurred in this paper. It must be made clear that stress and strain are two entirely distinct physical concepts, and that each one is defined independently. For elastic materials they are related by Hooke's law, which, correctly quoted, states that strain components are linear functions of stress components. This does not mean at all that there is a constant of proportionality between stress and strain in any direction. The mathematical development of Hooke's law leads to the concepts of Young's modulus and Poisson's ratio, which are taken for granted in this paper.

---

[14] Eng. Asst., Vega Aircraft Corp., Burbank, Calif.

When the author states (see heading, "Fundamental Problems of Stress in Terms of Strain"): "* * * If stress is proportional to strain * * *," he seems to establish some kind of Hooke's law for the material that he studies. However, this is only apparent because his "stress" is proportional to strain by definition, and a law between two interdependent quantities cannot have any physical meaning.

Using the notation and definitions of the author, it easily can be seen that the statement (see heading, "Stress and Intensity of Force") that "* * * f may be greater or less than p by a percentage not greater than Poisson's ratio, * * *" is not correct. In the case of Fig. 4, for $\alpha \doteq 0$, $p_a = 0$ from Eq. 11*a*, and $f_a = -\mu p$ from Eq. 8*b*. The difference $p_a - f_a = \mu p$, expressed as a percentage of f_a, is 100, and as a percentage of p, infinity.

Referring to Fig. 3, it is very possible that some materials tested in compression fail when the transverse strain is equal to the strain in the direction of the load at failure for a tension test. This amounts to stating that in such cases strain, and not stress, determines the failure of the material. However, the material does not fail in tension, because there is no tensile force transmitted through planes parallel to the direction of compression. Perhaps the author should refer to failure by elongation.

Under the heading, "Shear and Stress," the author states that "* * * (*a*) in materials strained by exterior forces including shearing forces, only two kinds of stresses are set up—compressive stresses and tensile stresses—and (*b*) shear is accompanied by and resisted by internal forces of tension and compression." Under the heading, "Shear and Stress," the well-known fact is shown that (in two-dimensional stress distributions) there exist at any point two planes, perpendicular to each other, where no shear stresses exist and where normal stresses are maximum and minimum. From this it cannot be concluded, as the author does, that external forces are resisted within the material only along the two aforementioned planes (principal planes of stress). The principal planes are only two of an infinity of planes passing through a point. Stresses, shear stresses as well as normal ones, act along each of the infinite planes, and the material resists along each of the infinite planes. The principal planes are particularly interesting, but the planes of maximum shear (at 45° with the principal planes) are no less important. Shear stresses are neither "imaginary" nor "inexplicable" but are just as real as the principal stresses, and there is no proof, in this paper or elsewhere, that the material must fail along one of the principal planes. It may or it may not. It is perfectly conceivable, and verified by tension tests in steel, that materials may fail along the planes of maximum shear. Therefore conclusion (*b*), which should embody the main result of this paper, is incorrect.

Conclusion (*a*) is correct for stresses as defined by the author. However, since such stresses actually represent only strains, conclusion (*a*) would be more correctly stated if "strains" were read instead of "stresses." It has been proved in fact that stresses (as defined by the Theory of Elasticity) do not depend on Poisson's ratio, in two-dimensional stress distributions, except in very particular cases.

In conclusion, not only does this paper present no new results, but it is extremely confused, and at odds with the fundamentals of the Theory of Elasticity.

I. NELIDOV,[15] M. AM. SOC. C. E.—The essential claims raised in this paper may be summarized briefly as follows:

1. Poisson's ratio should be considered in computations;
2. Shearing stress and strength are misnomers; and
3. Failure occurs when material is overstressed in tension.

In reading this paper, it is impossible to judge from its title or content whether the problem treated by the author refers to all materials or just to a particular one. It follows from the text, however, that, since the theory deals with the compression force acting on a prism, one may judge that the paper is intended for concrete. Some of the author's theses and conclusions seem to refer to concrete only, or, more generally, to brittle materials. However, since the author does not limit the scope of the paper, the result is confusing.

Referring to claim 1, one may regret that Poisson's ratio sometimes is unduly neglected in computations, and it is likewise without dispute that some engineers even raise their eyebrows at a mention of the so-called "true stresses." The term "true stress" is used herein according to the definition[16] of a stress formulated by the late Mansfield Merriman, M. Am. Soc. C. E., including the effect of Poisson's ratio, which the author calls simply "stress" and in contradistinction to Mr. Merriman's "apparent stress," which the author calls "force intensity." The terms chosen by Mr. Merriman are preferred by the writer because the term ("force intensity") used by the author is a somewhat more complicated one, whereas the term "stress" is so deeply rooted in terminology that to call it "apparent stress" or "true stress" will not be difficult. The stress is "apparent" because it results only from division of a force by an area without considering other factors. The "true stress" considers the effect of actual deformations.

However, a term is only a matter of choice of words. The principal thing should be the cognizance of the facts. From this point, the author's terminology will be used.

The importance of considering Poisson's ratio has been stated by the writer elsewhere,[17] at which time the "stress" in tension in a high buttress in the example chosen was found to be as high as 120 lb per sq in. in tension. The significance of neglecting this effect cannot be underestimated.

Eq. 10 and the effect of the Poisson's ratio,[18] as shown in Fig. 10, can be obtained directly from Mohr's circle.

[18] "Mohr's Circle with Poisson's Ratio," by I. Nelidov, *Western Construction News and Highways Builder*, November 25, 1932, p. 666.

Thus, $f_n = f_{\max} - 2\,s_{\max}\cos^2\alpha$. From the problem by the author: $f_{\max} = p$; and $f_{\min} = -\mu\,p$. From Mohr's circle: $s_{\max} = \dfrac{f_{\max} - f_{\min}}{2} = \dfrac{1+\mu}{2}\,p$, or

$$f_n = p\left[1 - (1+\mu)\cos^2\alpha\right]\ldots\ldots\ldots\ldots\ldots\ldots(27)$$

It is evident that Eq. 27 is applicable only to materials that have a limit of proportionality of stress and strain and not to materials that have a modulus of elasticity which is a curved line from the beginning of loading. In this connection one wonders what the author has meant by his statement following Eq. 10 that "* * * Eq. 10 is applicable for all materials of construction up to the strains at which rupture occurs."

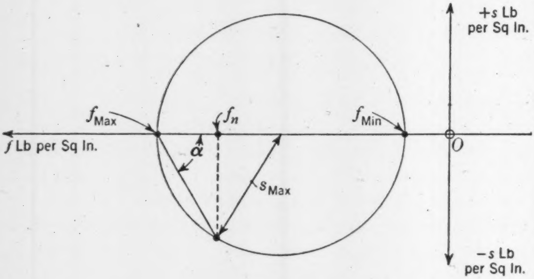

FIG. 10

In regard to claim 2, stated at the beginning of this discussion, the writer wishes to declare that, from a theoretical and conventional standpoint, one cannot dispose so easily of the terms "shearing stress" and "shearing strength," because tangential forces and resistance will always exist, disregarding the designer's wishes to be rid of them. It is true that in actual practice the true shearing force or stress is never approached because a case of true shear will call for two forces acting one against the other and nearly collinear. In actual problems shearing forces will have a lever arm always, thus forming a couple; or they will have a bending moment, with resulting tensile stress at right angles to the direction of shear. The reason that the term "shearing strength" exists is explained in the same way as the reason for the existence of the term "compressive strength." Neither of these terms has any real meaning, because both are obtained from the simplest possible way of loading a specimen, one in shear, another in direct compression. If one is desirous of finding the correct factor of safety for a material, one will have to test a specimen under the same conditions of lateral support in regard to such tension, compression, or shear as will exist in the full-sized structure and thus will determine its strength. Because of the complications involved in this kind of test, it is very seldom made; instead, judgment is supported by simple compressive, tensile, or other tests.

That definite shearing stresses exist if Poisson's ratio is considered can be proved from Fig. 3, concerning which the author quotes the well-known fact that, "if friction [at the ends of a prism under compression] be eliminated by effective lubrication, the diameter of the entire cylinder will expand and ultimately the material will fail by cracking parallel with the direction of compression * * *." What actually happens in this case is that the tensile strength of the material is greater than the shearing strength, which is zero at both ends. The specimen fails in shear at both ends due to lateral expansion long before it fails "in tension." However, the shearing failure is not conspicuous and is not noted, but the tensile failure is manifest and thus is wrongly named. If the ends are cast monolithically with the end supports, or even just restrained, as in ordinary compression tests, then tensile strength will become smaller than the shearing strength and failure will occur in tension on inclined planes, which again is erroneously called "shear failure." Shearing stress or force intensity is inseparable from tensile or compressive stress because it simply manifests angular distortion just as tensile or compressive stress manifests axial deformation.

Therefore, the writer disagrees with Mr. Woodard in regard to claim 2 and thinks that, conventionally, theoretically, and actually, the author's shearing "force intensity" and "stress" do exist and are not misnomers. In regard to claim 3 the following may be said:

There is danger in making quick conclusions regarding the stress condition and possible cause of failure based on the assumption of a uniform distribution of a stress. To illustrate, consider the prism used by the author of finite dimensions and under compressive load. His reasoning applies only to a theoretical case of a unit area wherein a force p is acting on an elementary cube under consideration. In an actual prism, a total force P is not even equally distributed on the bearing ends, and much less within the prism. Therefore, the generalization by the author derived from his elementary formula to explain the cause of failure of a finite body may be considered as a first step only. A further step would be to determine a true distribution of stresses and to observe the points where various stresses are excessive. Failure may begin at any of these points, and it will always be progressive. Usually, since the speed of progress of a failure is great, it is considered that the entire section failed at once, and some "average" stress is computed which caused this failure. This may be practical, but it is incorrect and the discrepancy is demonstrated best by failures of machine parts. These fail in many instances when the "average" stresses appear to be perfectly safe.

The best illustration of the writer's attitude on the causes of failure may be given in the following quotation from S. Timoshenko[19] (to which the writer has nothing to add):

> "In the case of brittle materials such as cast iron, fracture occurs without appreciable plastic deformation and on a cross-section perpendicular to the direction of tension. This is a separation failure. A specimen of a ductile material such as mild steel undergoes considerable plastic deformation and reductions in cross-sectional area due to sliding along planes inclined 45° to the axis of the specimen before fracture occurs. This is sliding failure. * * * If the resistance to sliding is greater than the re-

---

[19] "Strength of Materials," by S. Timoshenko, Pt. II, 1930 Ed., p. 671.

> sistance to separation, we have a brittle material and fracture will occur as a result of overcoming cohesive forces without appreciable deformation. If the resistance to separation is larger than resistance to sliding, we have a ductile material. * * * The relation between the resistance to separation and the resistance to sliding does not remain constant for the same material. It depends very much upon the velocity of deformation and upon the temperature at which a test is made. There are evidences that the resistance to sliding increases as the velocity of deformation increases and as the temperature is lowered. At the same time the resistance to separation is not affected to the same degree by these two factors. This would explain why a bar of a metal such as zinc can be bent like a ductile material under slow loading while the same bar fractures without plastic deformation if the loading is applied suddenly. * * * The type of fracture depends also on the manner of testing. If the loading is of such a nature that fracture due to separation is prevented, a considerable plastic deformation may be obtained in a material usually considered brittle. * * * Likewise, a ductile material may have a fracture of the brittle type if the form of the specimen or the type of stress distribution is such that plastic deformations, due to sliding, are prevented."

Based on his own previous statements and the foregoing quotation, the writer does not agree with Mr. Woodard's conclusions condensed in claim 3.

To summarize, the writer is of the opinion that the author has raised an important issue in the use of Poisson's ratio, but his conclusions about shear stresses and causes of failure cannot be verified.

BERNARD L. WEINER,[20] M. AM. SOC. C. E.—The laws of static equilibrium hardly can be questioned, at this late date. Although the mathematical theory of elasticity is not so well known, it is too well recognized to be questioned lightly. Finally, the ellipse of stress has been accepted for so long that it can be questioned only by offering the most exhaustive proof. The author's work is in direct contradiction of all three and, without exhaustive proof, is suspect. There can be little doubt that his work is in error.

Mr. Woodard proceeds to find the strains normal to a plane at an angle to an axial force acting on a rectangle and then argues that since stress is proportional to strain in the same direction, the stress is E times the strain. Let it be said once, and for all, that stress and strain in the same direction are not directly proportional to each other—except in one special case. The general case, which can be found in any standard text on the mathematical theory of elasticity and in texts on advanced mechanics of materials, is:

$$\left.\begin{aligned} \delta_1 &= \frac{p_a}{E} - \frac{\mu}{E}(p_b + p_c) \\ \delta_2 &= \frac{p_b}{E} - \frac{\mu}{E}(p_a + p_c) \\ \delta_3 &= \frac{p_c}{E} - \frac{\mu}{E}(p_b + p_c) \end{aligned}\right\} \cdots\cdots\cdots\cdots (28)$$

---

[20] Designer, Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

and

$$\left.\begin{aligned} \phi_1 &= \frac{s_a}{G} \\ \phi_2 &= \frac{s_b}{G} \\ \phi_3 &= \frac{s_c}{G} \end{aligned}\right\}\cdots\cdots\cdots\cdots(29)$$

in which s = unit shear; G = the shear modulus of elasticity; ϕ = angle of shear strain; and δ = unit elongation.

If only one force and its reaction are acting, it is true that stress and strain parallel to the force are proportional; but, even in this case, strain perpendicular to the force exists without stress. If the stresses are unknown but the strains are given, the former can be found by solving the general equations of the stress-strain relationship. If the strains in this simple case were substituted in these equations, p_a would be the only one having a finite value equal to p_a, of course, and p_b and p_c would equal zero. This is a matter of simple algebra—and no mysterious theories are involved.

What the author is really doing is to revive the old exploded theory of "virtual stress" as against "real stress." This conception has been renamed "intensity of force" and "intensity of stress" but is otherwise the same idea derived from the fallacy that stress and strain in the same direction are directly proportional. In his "Mechanics of Materials,"[21] Mr. Merriman made the same error probably more than half a century ago, and others have followed in his footsteps from time to time. Many "odd" results can be obtained, of course, by the use of Eq. 8b, but only one is necessary to show the error. If, in this equation, angle α is set equal to zero, $f_n = -(1 + \mu)\,p$; but since the plane that makes a zero angle with the only applied force is parallel to, and may be, an external surface, it cannot have any stress on it. Other results, although not so obvious, are equally incorrect.

Since the equation $\frac{\delta_n}{\delta} = \frac{f_n}{p}$ is incorrect, the results derived for the intensity of stress have no meaning. The author should have taken warning that something was radically wrong with his theory. No matter what else is involved, the fundamental laws of static equilibrium still must be satisfied under any and all conditions and a summation of the stresses on a plane must equal zero (taking external forces, if any, into account). As a matter of fact, for the simple case treated in Fig. 4, the intensity of force is also the true and synonymous intensity of stress and the author's version is merely a fallacy that does not exist.

There is no need to go into this part of the paper any further since the true equations have been developed in standard texts on the mathematical theory of elasticity and in texts on advanced mechanics of materials. It may be well to point out, however, that, for the general case, the stresses can be found only by solving partial differential equations. The fact that this is usually the case is rather unfortunate because, in the present state of knowledge of this type of equations, most of them cannot be solved directly. John Prescott,[22] in his "Applied Elasticity," makes this point very clear.

---

[21] "Mechanics of Materials," by Mansfield Merriman, 11th Ed., John Wiley & Sons, Inc., New York, N. Y., 1914.

Most of the author's equations are merely variations of the ellipse of stress derived by very laborious reasoning; and, when he does not tie them up with the fallacy of virtual stress (intensity of stress), they are correct. The derivations are arrived at much more simply in standard texts. However that may be, although the author's equations—without the virtual stress fallacy—are correct, his interpretations of the meaning of the equations are incorrect. Shear does exist and the reasoning which leads to the ellipse of stress simply states that a force which produces tension on one plane, compression on another, may, and usually does, produce shear on the same or other planes. Instead of denying the existence of shear, the real interpretation is that the material must be strong enough to resist the stresses in all directions, whatever they may be —tension, compression, or shear, or a combination of direct stress and shear. It might just as well be argued that compression does not exist in certain members of a truss, because the forces really are resisted, of course, by tension in other members. In Fig. 4, if line A-A were a cleavage plane, the upper part would certainly slide over the lower and it would be a sliding or shear failure.

According to the author's discussion in connection with Fig. 3, the block under compression would fail in tension—if the bearings were lubricated. Quite the contrary—as is well known in statically indeterminate stress analysis, only when "normal" deformation is prevented, are stresses produced. Deformation itself, unrestrained, does not produce any stress. The old illustration of the unrestrained bar which is heated and of the same bar which is confined between rigid abutments and also heated is sufficient to prove the fallacy of the author's contention. In Fig. 3, the very fact that the expansion of the diameter as measured by Poisson's ratio is prevented by the friction between the bearings and the block produces the stress at right angles to the force. The stress induced, with some modification that is unnecessary to go into for the present purpose, is the same as if the unstressed block were deformed by a system of radial, transverse forces by an amount equal to the Poisson expansion. Here again, of course, the fallacy lies in the incorrect assumption that stress and strain in the same direction are always directly proportional to each other.

Although the discussion in connection with Fig. 3 is in error, it does call attention to a problem which needs to be solved. The lateral stresses produced by the restraint will produce other stresses, in turn, and the solution, the writer ventures to guess, will not be either simple or easy. Further study is necessary to solve this problem, which may yield valuable results.

Since most of the paper is merely a laborious variation of the ellipse of stress erroneously combined with Poisson's ratio, most of the conclusions are invalid. The results derived in Table 1 are invalid also, but, by accident, they are probably not very seriously in error because of the fact that the applied tensions and shears are of the same order of magnitude. This fact tends to cancel the error. Hence, whatever meaning the data may have, they are very likely approximately correct.

---

[22] "Applied Elasticity," by John Prescott, Longmans, Green, London, 1924.

This paper is merely a compilation of old and new fallacies; and it controverts established fact.

Richard W. Albrecht,[23] **Jun. Am. Soc. C. E.**—A refinement of the Maximum Strain Theory of failure is presented in this paper. The usual method of treating this theory is to find the unit strain due to the maximum principal stress, modify this value by the strain caused by the stress at right angles to the maximum principal stress, and call the resulting value the maximum strain. The paper presents the method of first finding the unit strain in terms of the normal stress and the stress at right angles to this stress, and then maximizing the result to obtain the maximum unit strain. Although the latter method is theoretically more accurate, the difference between the values obtained in this manner and the values obtained in the usual manner is negligible and does not justify the use of the more cumbersome equations evolved. The evaluation of Poisson's ratio and the modulus of elasticity are more approximate than the assumption made in the usual derivation of the Maximum Strain Theory, which makes the more accurate assumption useless except for a mathematical derivation of the theory. A comparison of the values of the angle β and the maximum tensile and compressive unit stresses as obtained by the use of Eqs. 21 and 15 (which differ from the tabulated values in the paper) and as obtained by the usual Maximum Strain Theory, is given in Table 6. All differences are within the limits ordinarily to be expected when a slide rule is used.

TABLE 6.—COMPARISON OF MAXIMUM AND MINIMUM STRESSES, IN POUNDS PER SQUARE INCH, COMPUTED BY EQS. 21 AND 15 AND BY THE USUAL MAXIMUM STRAIN THEORY

(For Values of Applied Shear and Tension, See Table 1)

Test No.	Eqs. 21 and 15			Usual Maximum Strain Theory		
	β	Computed Stress		β	Computed Stress	
		Tensile	Compressive		Tensile	Compressive
3SA3	63° – 39′	22,480	11,950	63° – 40′	22,470	11,970
3SA24	62° – 56′	21,910	11,930	62° – 57′	21,890	11,900
3SA15	60° – 24′	21,560	12,715	60° – 26′	21,540	12,690
3SA18	60° – 59′	21,950	12,720	60° – 59′	21,930	12,700
3SA21	61° – 27′	22,280	12,720	61° – 27′	22,290	12,720
3SA4	57° – 14′	22,720	14,880	57° – 15′	22,700	14,850
3SA20	59° – 22′	24,220	14,780	59° – 23′	24,220	14,760
3SA10	56° – 0′	21,700	14,800	56° – 0′	21,730	14,820
3SA17	55° – 41′	21,520	14,850	55° – 41′	21,510	14,855
3SA7	45° – 0′	17,420	17,420	45° – 0′	17,420	17,420

In Conclusion (*b*) the author states:

> "Shear intensity is not a stress but is always accompanied and resisted by diagonal tensile or compressive stresses or both."

---

[23] Instr., School of Technology, College of City of New York, New York, N. Y.

This statement is correct only when two specific planes at right angles to each other are considered. There are an infinite number of other planes on which a tendency to slide exists. If the material is unable to furnish the necessary resistance to sliding but is at the same time able to furnish the necessary resistance to compression or tension, a sliding failure will occur along the plane on which the maximum shearing stress exists. Such failure occurs in a brittle material subjected to compression alone. Theodor von Kármán, M. Am. Soc. C. E., and Robert Böker conducted extensive studies of the theories of failure of a brittle material. Their results indicate that the failure of a material may be controlled by a dual law, a tensile or splitting failure occurring with certain stress combinations and a shearing or sliding failure occurring with other combinations.[24]

The author (see heading "Stress and Intensity of Force") "enlists with the partisans of the Maximum Stress and Maximum Strain Theories of failure as opposed to the Maximum Shear Theory, the Maximum Distortion Energy Theory, and the Maximum Strain Energy Theory." Can it be said that these theories are opposed to each other? Rather, should it not be said that these theories are various attempts to explain on a rational basis the failure of engineering materials? As no one of these theories deals with the atomic or molecular structure of the material, each theory makes certain basic assumptions which may or may not be exactly correct. The best test of any theory is its agreement with observed data. The five theories of failure under discussion are as follows:[25]

Maximum Stress Theory.—

$$\sigma_w = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + (\tau_{xy})^2} \quad \ldots\ldots\ldots\ldots (30a)$$

Maximum Shear Theory.—

$$\sigma_w = 2\sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + (\tau_{xy})^2} \quad \ldots\ldots\ldots\ldots (30b)$$

Maximum Strain Theory.—

$$\sigma_w = (1 - \mu)\left(\frac{\sigma_x + \sigma_y}{2}\right) + (1 + \mu)\sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + (\tau_{xy})^2} \ldots (30c)$$

Strain Energy Theory.—

$$\sigma_w = \sqrt{(\sigma_x)^2 - 2\,\mu\,\sigma_x\,\sigma_y + (\sigma_y)^2 + 2\,(1 + \mu)\,(\tau_{xy})^2} \quad \ldots\ldots (30d)$$

Distortion Energy Theory.—

$$\sigma_w = \sqrt{(\sigma_x)^2 - \sigma_x\,\sigma_y + (\sigma_y)^2 + 3\,(\tau_{xy})^2} \quad \ldots\ldots\ldots\ldots (30e)$$

---

[24] "Die Mechanik der bleibenden Formänderung in kristallinisch aufgebauten Körpern," by Robert Böker, *Mitteilungen über Forschungsarbeiten auf dem Gebiete des Ingenieurwesens*, Vol. 176 and 176, 1915 (for reference to this subject, see "A Study of the Failure of Concrete under Combined Compressive Stresses," by F. E. Richart, A. Brandtzaeg, and R. L. Brown, *Bulletin No. 185*, Univ. of Illinois, Urbana).

[25] "Mechanical Properties of Materials and Design," by Joseph Marin, McGraw-Hill Book Co., Inc., 1942.

For the illustration used in the paper, in which $\sigma_y = 0$ and $\mu = 0.33$, Eqs. 30 reduce to the forms:

Maximum Stress Theory.—

$$\sigma_w = \frac{\sigma_x}{2} \pm \sqrt{\left(\frac{\sigma_x}{2}\right)^2 + (\tau_{xy})^2} \qquad (31a)$$

Maximum Shear Theory.—

$$\sigma_w = 2\sqrt{\left(\frac{\sigma_x}{2}\right)^2 + (\tau_{xy})^2} \qquad (31b)$$

Maximum Strain Theory.—

$$\sigma_w = 0.335\,\sigma_x + 1.33\sqrt{\left(\frac{\sigma_x}{2}\right)^2 + (\tau_{xy})^2} \qquad (31c)$$

Strain Energy Theory.—

$$\sigma_w = \sqrt{(\sigma_x)^2 + 2.66\,(\tau_{xy})^2} \qquad (31d)$$

Distortion Energy Theory.—

$$\sigma_w = \sqrt{(\sigma_x)^2 + 3\,(\tau_{xy})^2} \qquad (31e)$$

A comparison of the values of the failure stresses, σ_w, as found by the various theories, and the ratio of this stress to the proof stress, σ_p, is given in Table 7.

TABLE 7.—COMPARISON OF FAILURE STRESSES COMPUTED BY VARIOUS FAILURE THEORIES

(For Values of Applied Shear and Tension, See Table 1)

Test No.	$\frac{\sigma_x}{\tau_{xy}}$	FAILURE STRESS, σ_w (LB PER SQ IN.)					$\frac{\text{FAILURE STRESS}}{\text{PROOF STRESS}} = \frac{\sigma_w}{\sigma_p}$				
		Stress theory	Shear theory	Strain theory	Strain energy theory	Distortion energy theory	Stress theory	Shear theory	Strain theory	Strain energy theory	Distortion energy theory
3SA3	1.135	20,800	25,900	22,470	22,800	23,800	0.889	1.107	0.960	0.984	1.018
3SA24	1.445	20,150	25,400	21,890	22,300	23,250	0.861	1.085	0.935	0.952	0.996
3SA15	1.192	19,470	25,740	21,540	22,350	23,250	0.832	1.100	0.920	0.955	0.996
3SA18	1.249	19,920	26,040	21,930	22,700	23,600	0.839	1.113	0.936	0.970	1.009

3SA17	0.782	18,655	27,360	21,510	23,000	24,200	0.797	1.168	0.918	0.983	1.034
3SA7	0	13,100	26,200	17,420	21,400	22,700	0.560	1.120	0.745	0.915	0.970

In Fig. 11, this ratio is plotted as ordinate against the ratio of applied tension to applied shear as abscissa. An attempt has been made to plot probable curves for the comparisons of the various theories of failure they may give, although data are lacking for enough points to give conclusive curves. These curves show the most conservative theory for the test conditions to be the Maximum Shear Theory, and the least conservative to be the Maximum Stress Theory.

The theory that gives results closest to the observed data is the Distortion Energy Theory.

The application of these theories to the data given in the paper is of doubtful value as they purport to explain only the failure of elastic action, whereas the stresses given in the paper are apparently for complete failure, being considerably higher than the 17,500 lb per sq in. yield point of the material.

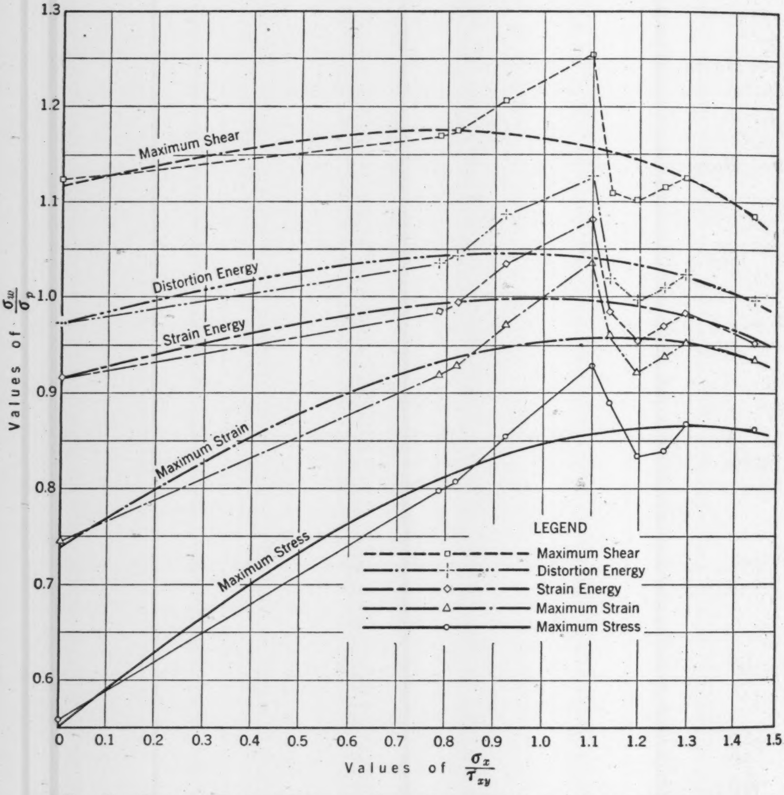

FIG. 11.—RATIO OF FAILURE STRESS TO PROOF STRESS BY VARIOUS FAILURE THEORIES

DUFF A. ABRAMS,[26] M. AM. SOC. C. E.—It should not be forgotten that strength of materials is a "land of make believe." Approaching the subject from the mathematical viewpoint, one must assume a material with idealized properties and load conditions that have little relation to anything in nature. Assumptions generally include isotropic material, constant elastic properties, and simple axial stress within the elastic range. Approaching the subject from the physical viewpoint, one soon encounters distinct limitations to experimental methods that lead to many contradictions. Probably no one knows the actual strength of any material. Determinations that have been made are based on arbitrary, and frequently unskillful test methods, all of which conceal important assumptions or fallacies that have been generally overlooked or ignored.

---

[26] Cons. Engr., New York, N. Y.

Most tests have been made in tension; yet a cursory consideration will show that pure and uniform tension is never developed. If such questions as boundary conditions, surface imperfections, localized stresses, sustained, reversed or repeated loads are considered, all the usual concepts of strength of materials must be modified or discarded.

As early as 1858 A. Wöhler[27] made fatigue tests on steel bars that failed at loads much lower than their strength as determined by once-applied loads. Investigations of fatigue of modern steels[28,29] showed that with 100,000,000 reversals of stress failure occurred at 40% to 70% of the usual tensile strength.

In 1907 J. L. Van Ornum,[30] M. Am. Soc. C. E., showed that both concrete prisms in compression and reinforced concrete beams in flexure failed under 10,000 to 32,000 repetitions at about 50% of the load they would withstand if loaded to their ultimate strength at once.

In 1920, A. A. Griffith[31] showed that the tensile strength of a certain glass varied enormously with the diameter of the specimen. For diameter 0.04 in. the strength was 24,900 lb per sq in.; and, for a diameter of 0.00013 in., it was 491,000 lb per sq in. Griffith estimated that if this glass were drawn to molecular diameter, it would have a tensile strength of 1,600,000 lb per sq in. Tests of metal wires have shown somewhat similar results.

The foregoing examples emphasize some of the properties of materials that are concealed by the "factor of ignorance," usually referred to as a "factor of safety."

Effect of Elastic Beds on Compressive Strength.—During the past century, considerable literature has accumulated on the effect of the end condition of test specimens on the compressive strength of cast iron, stone, concrete, brick, and similar materials. This problem is not so simple as indicated by Mr. Woodard's analysis; the evidence indicates that in addition to the end condition, the method of failure of short compression specimens is influenced by: (*a*) The rigidity of the material under test; (*b*) the size of specimen; and many other factors.

In 1773, C. A. Coulomb[32] concluded that a material loaded in compression will fail along a series of planes at 45° with the horizontal; in the case of a cube, six equal tetrahedra are formed, each having as its base one face of the original cube. Observation shows that, in general, this so-called pyramidal fracture occurs only in materials of comparatively low strengths, such as the weaker rocks, or mortars and concretes at early ages.

[32] *Mémoirs* of the Royal (French) Academy of Sciences, 1773, p. 343.

Mr. Woodard states with reference to this method of failure (see heading, "Fundamental Problems of Stress in Terms of Strain"):

> "* * * if friction be eliminated by effective lubrication, the diameter of the entire cylinder will expand and ultimately the material will fail by cracking parallel with the direction of compression, as indicated in Fig. 3."

In making early compression tests of building stones, it was customary to place thin sheets of lead under and over the test cube. The weakening effect of lead sheets was brought prominently to the attention of American engineers by the report of the Federal Commission of 1851 that was appointed to study marbles, etc., in connection with the extension of the U. S. Capitol; details are given in the architect's report that accompanied the message of President Millard Fillmore to the 32d Congress, 2d Session, in 1852. With reference to these tests it may be appropriate to quote from a paper dated 1873 by C. B. Richards:[33]

> "This Commission discovered the somewhat remarkable fact that the effect of pieces of sheet lead placed between the stone samples and the steel surfaces of the testing apparatus, was to occasion the failure of the specimen with about half the load it would sustain if pressed directly by the steel surfaces; that is, with the steel and stone surfaces in contact."

The findings of the Commission of 1851 on the use of lead sheets in testing building stone should be compared with the somewhat similar results in Mr. Woodard's compression tests of cement and mortar specimens with lubricated ends.

The effect on the strength of various end treatments of test specimens was brought out for stone cubes by Q. A. Gillmore,[34] the late W. C. Unwin,[35] Hon. M. Am. Soc. C. E., G. P. Merrill,[36] and by the tests made by the Chief of Engineers, U. S. Army[37]; and for concrete cylinders by D. V. Terrell, M. Am. Soc. C. E.,[38] and H. F. Gonnerman,[39] M. Am. Soc. C. E.

The effect of lubrication of the type used by Mr. Woodard on the strength and type of failure may be very different with different materials. Mr. Woodard's tests covered only the use of greased blotting paper. Sufficient data are available to throw much doubt on the author's conclusions when applied to the general case of short specimens in compression. Lubrication of the ends of specimens is not necessary to produce failure by "cracking parallel with the direction of compression." In 1859, W. Fairbairn and T. Tate[40] reported compression tests of glass cubes that showed this type of failure. They stated:

[40] "On the Resistance of Glass Globes and Cylinders to Collapse from Internal Pressure, and on the Tensile and Compressive Strength of Various Kinds of Glass," by W. Fairbairn and T. Tate, *Proceedings*, Royal Soc. of London, May 12, 1859.

> "The specimens were crushed almost to powder by the violence of the concussion, when they gave way; it, however, appeared that the fracture occurred in vertical planes, splitting up the specimen in all directions. Cracks were noticed to form some time before the specimen finally gave way; then these rapidly increased in number, splitting the glass into innumerable irregular prisms of the same height as the cube. Finally, these bent or broke, and the pressure, no longer bedded on a firm surface, destroyed the specimen."

From 1900 to 1912 there was a lively discussion of the effect of elastic substances interposed between the loading surfaces in compression in the *Proceedings* of the International Association for Testing Materials.[41,42,43]

Capping of Concrete Cylinders.—An elaborate investigation of methods of capping the tops of 6-in. by 12-in. concrete cylinders, conducted under the writer's direction in 1923, showed that the strength of concrete was reduced by practically all of the yielding materials used. The principal data of these tests are given in Table 8, rearranged from Mr. Gonnerman's report.[39] The standard method consisted of a neat cement cap about $\frac{1}{8}$ in. thick applied to the fresh concrete 2 to 6 hours after molding the cylinders, by means of a planed cast-iron cover plate.

The values at the tops of the columns of strength ratios in Table 8 are the compressive strengths for standard capping method; each of these was based on 49 to 58 tests. Some of the conclusions are:

(*a*) Cylinders capped just prior to test with gypsum or mixtures of cement and gypsum gave sensibly the same strength as the standard method using neat cement.

(*b*) In general, compressible materials caused a loss in strength; the greatest loss was in the strongest concrete.

(*c*) The loss in strength from the use of sheet lead was about the same for thicknesses varying from 1/16 in. to 3/16 in., and was sensibly the same as for blotting paper or cork. For the strongest concrete (4,500 lb per sq in. at 28 days) the strength ratios from these materials was about 0.75.

(*d*) The greatest reduction in strength was found with sheet rubber; for the 1/16-in. thickness the ratios for the strongest concrete were 0.47 to 0.65.

The strength ratios for blotting paper in these tests and for those of Mr. Woodard using grease and blotting paper are as follows (length of specimens, two diameters):

Tests by	Weakest specimens	Strongest specimens
Gonnerman	0.92	0.77
Woodard	0.72	0.66

[41] "Baumaterialeinkunde," 1900, by A. Föppl, p. 129, and by F. Kick, p. 177.

[42] "On the Resistance of Stone to Compression, with Elastic Substances Interposed between the Surfaces in Compression," by S. C. Pace, *Paper B. 10e*, Brussels Cong., International Assn. for Testing Materials, 1906.

[43] "On the Question of Friction between the Parallel End Surfaces of a Body and the Plates through which Pressure Is Applied," by H. I. Hannover, *Proceedings*, VIth Cong., International Assn. for Testing Materials, Paper $XXVII_7$, 1912.

It should be noted that in Mr. Gonnerman's tests only the tops of the cylinders were affected by the various capping materials and methods; if the bottoms had been treated in the same manner, the observed reduction in strength would probably have been nearly doubled.

TABLE 8.—COMPRESSION TESTS OF CONCRETE CYLINDERS, USING DIFFERENT CAPPING MATERIALS

Capping material	Time[a]	Thickness of caps (in.)	STRENGTH RATIOS, LB PER SQ IN.[b]

[a] Time of capping, in hours before test. [b] Cylinders were made of a mixture of four brands of portland cement purchased in Chicago, Ill. Values given are the averages of ten tests made on different days. [c] Flow about 220.

Tensile Strength of Mortar Briquets.—Mr. Woodard states (see heading, "Fundamental Problems of Stress in Terms of Strain"):

> "* * * the known tensile strength, divided by the observed compressive stress at time of failure equals Poisson's ratio as nearly as it can be determined."

This conclusion was based on tensile strengths of cement and mortar briquets of the form that are standard for cement tests,[44] and on compression tests of cylinders and prisms. If the quotient of these strengths equals Poisson's ratio, it was probably accidental. Several different methods of determining the tensile strength of mortars and concretes have been used. Each method gives a different tensile strength; and the briquet is probably the most unsatisfactory form of all. Since mortars fail at an elongation of about 0.001, and the most-stressed section of a briquet is only a fraction of an inch long, it is obvious that there is little opportunity for the stress to become uniformly distributed across the minimum section. The briquet represents a clear case of eccentric loading.

---

[44] "Standard Methods of Sampling and Physical Testing of Portland Cement," A.S.T.M. Standards, Pt. II, 1942, p. 33.

C. L. Durand-Claye[45] in 1895 gave an analytical method of calculating the variations of stress across the minimum section of a briquet. A. Föppl[7] in 1896 showed wide variations in the stresses in a briquet by measurements on an india rubber model. The late J. B. Johnson,[46] M. Am. Soc. C. E., in 1897 applied Durand-Claye's method of analysis to briquets of the form used in the United States. E. G. Coker,[47] in 1912 showed the wide range in these stresses by means of photoelastic observations on glass or celluloid models; and similar methods were used in 1939 by F. O. Anderegg, Royal Weller, and B. Fried.[48] These studies showed a high concentration of stresses at the edges of the waist of the U. S. Standard briquet, as follows:

Authority	Date	Ratio of maximum to average stress
Johnson	1897	1.54
Coker	1912	1.70
Anderegg	1939	1.78
Average		1.67

The failure of the briquet results from a tearing action rather than from a true tensile stress. As the cement becomes older and stiffer, the discrepancy between the indicated and the true strength becomes more and more pronounced. This accounts for phenomena that have been observed many times —namely, a rapid increase in tensile strength of cement mortars to 1 to 2 months followed by a gradual falling off, until the indicated briquet strength at 1 year was generally less than at 7 days, whereas the compressive strength of the same mortars and of concrete from the same cement continued to increase indefinitely, as long as the specimens did not dry out.

The briquet is a carry-over from the infancy of the art. It was adapted by John Grant[49] in London in 1859 from the practice of stone testing, and has undergone little change during the succeeding 84 years. In Germany the briquet was abandoned in favor of the cube for cement mortar tests a generation ago. The inadequacies of the briquet have been commented on by a number of American writers in addition to those already referred to.[50,51,52] Erroneous attempts to reconcile the composition of cement and the behavior of concrete with the falling-off in briquet strength are responsible for much of the confusion that has characterized the history of cement and concrete technology in the United States.

Tensile and Flexural Strength of Concrete.—The difficulties of determining the tensile strength of concrete may be demonstrated by data from a paper[53] by H. F. Gonnerman and E. C. Shuman, Assoc. M. Am. Soc. C. E., in which an attempt was made to determine the relation between compressive, flexure, and tensile strength of the same concrete. Table 9 gives compressive strengths of 6-in. by 12-in. cylinders for three water-cement ratios at ages from 3 days to 1 year, together with values for modulus of rupture and tension expressed as fractions of the compressive strength. Tension tests were made by applying loads to 6-in. by 18-in. cylinders by means of heavy cylindrical shackles clamped to the ends of the cylinder. This method is subject to the same criticism as the briquet, in that it does not apply a uniform tensile stress across the section of the cylinder. Flexural tests were made by loading plain concrete beams (7 in. by 10 in. by 38 in.) at the 1/3 points of a 36-in. span.

TABLE 9.—COMPRESSION, TENSION, and FLEXURE OF PLAIN CONCRETE[a]

Water-cement ratio	AGE AT TEST				
	3 Days	7 Days	28 Days	3 Months	1 Year
(*a*) COMPRESSIVE STRENGTH, POUNDS PER SQUARE INCH					
0.68	2,000	3,100	4,710	6,460	7,420
0.76	1,560	2,620	4,460	5,710	6,720
0.87	1,070	1,900	3,560	5,130	6,000
Average...	1,540	2,540	4,240	5,770	6,710
(*b*) RATIO OF TENSION TO COMPRESSION					
0.68	0.105	0.089	0.081	0.073	0.077
0.76	0.112	0.092	0.081	0.073	0.078
0.87	0.126	0.116	0.089	0.081	0.072
Average...	0.114	0.099	0.084	0.076	0.076
(*c*) RATIO OF MODULUS OF RUPTURE TO COMPRESSION					
0.68	0.177	0.154	0.135	0.114	0.114
0.76	0.214	0.170	0.135	0.132	0.125
0.87	0.248	0.196	0.164	0.141	0.132
Average...	0.213	0.173	0.145	0.129	0.124
(*d*) RATIO OF TENSILE STRENGTH TO MODULUS OF RUPTURE					
....	0.54	0.56	0.58	0.59	0.61

[a] Mix, Portland cement to total aggregates was 1 to 4 by volume. Specimens were moist cured and each value is the average of five tests.

The modulus of rupture of beams and the tensile strength varied with both water-cement ratio and age; at 28 days the average modulus of rupture was 0.145 and the average tensile strength was 0.084 of compressive strength. According to Mr. Woodard's analysis, all of these values represent Poisson's ratios; but it is seen that the values varied from 0.072 for the 1-yr concrete in tension to 0.248 for the 3-day concrete in bending. The flexural strength ratios more nearly correspond to the generally-accepted values for Poisson's ratio.

---

[53] "Compression, Flexure and Tension Tests of Plain Concrete," by H. F. Gonnerman and E. C. Shuman, *Proceedings*, A.S.T.M., Vol. 28, Pt. II, 1928, p. 527.

Particular attention is called to the values in Table 9(*d*), which show that the average tensile strength ranged from 0.54 of the modulus of rupture at 3 days to 0.61 at 1 year. These values correspond closely to the value reported herein under "Tensile Strength of Mortar Briquets," where it was shown that the maximum stress at the edge of a briquet was 67% higher than the average, and indicate that Mr. Woodard's value of Poisson's ratio as computed from the tensile strength of briquets and compression tests of prisms is 67% too high.

Standard Compression Test of Concrete.—Since 1921 American engineers have followed generally the method of compression tests of concrete that was adopted in that year by the American Society for Testing Materials,[54] in which the load is applied directly to the plane ends of the cylinders. For the usual sizes of aggregates, cylinders 6 in. in diameter and 12 in. long are used; for larger aggregates 8-in. by 16-in., or larger, cylinders are used; the U. S. Bureau of Reclamation has used 36-in. by 72-in. cylinders in making compression tests of concrete containing gravel graded up to 9 in.[55]

Mr. Woodard suggests (see "Conclusions") that this method:

> " * * * should be revised to eliminate friction which can be done easily, or a correction factor should be determined to apply to the results of tests as now made."

This suggestion seems to the writer of doubtful merit for several reasons: (*a*) Basing design stresses on the 28-day compressive strength of concrete is purely arbitrary; (*b*) concrete in structures is seldom subjected to the type of compressive stress encountered in a standard test cylinder; (*c*) testing concrete in the form of 6-in. by 12-in. cylinders that have been moist cured for 28 days at room temperature is conventional; quite different strengths would be obtained if other sizes of cylinders or if another ratio of length to diameter were used, or if the age, curing conditions, or rate of loading were changed; (*d*) other factors being equal, the early strength of concrete depends to a large extent on the composition and fineness of the Portland cement.

Effect of Size of Concrete Cylinder.—Compression tests by the U. S. Bureau of Reclamation[55] on concrete cylinders with length equal to two diameters showed the following strength ratios, considering the 6-in. by 12-in. cylinder as 1.00:

Diameter of cylinder, in inches	Strength ratio
2	1.09
3	1.06
6	1.00
8	0.96
12	0.91
18	0.86
24	0.84
36	0.82

---

[54] "Standard Method of Test for Compressive Strength of Concrete," *A.S.T.M. Standards*, Pt. II, 1942, p. 328.

[55] "Concrete Manual," U. S. Bureau of Reclamation 1942.

This gives an extreme range from the lowest to the highest of 33%. Doubling the diameter was accompanied by a loss of 7% in terms of the "standard" strength of 6-in. by 12-in. cylinders.

Composition and Fineness of Cement.—The way in which the early strength of concrete is increased by improved compound composition and greater fineness is illustrated by parallel tests by E. Gruenwald[56] on normal and high-early-strength Portland cements of 1938. Typical results are summarized in Table 10. These tests were made on 6-in. by 12-in. cylinders using five sacks of cement per cubic yard, 2-in. slump, and water-cement ratio 0.88, by volume.

TABLE 10.—STRENGTH OF CONCRETE USING TYPICAL NORMAL AND HIGH-EARLY-STRENGTH PORTLAND CEMENTS

Portland cement	Tricalcium silicate (%)	Surface area (sq cm per g)	COMPRESSIVE STRENGTH CONCRETE (LB PER SQ IN.)				
			1 Day	3 Days	7 Days	28 Days	3 Months
Normal	47	1,745	480	2,180	3,075	4,675	4,915
High-early	58	2,440	1,795	3,720	4,360	4,915	5,415

An unpublished study of the literature by the writer shows that the average 28-day strength of moist-cured concrete made of American Portland cements, of water-cement ratio 0.80 by volume (0.53 by weight), was about 2,500 lb per sq in. in 1918, but that it increased to 5,000 lb per sq in. in 1940. This resulted from a general improvement in the compound composition of the cement (more uniform burning at higher temperatures) and to finer grinding. This increase would no doubt have continued to the present, had it not been for the lower quality of Portland cement ordered by the War Production Board in August, 1942.[57]

It is well known that the accuracy of the plane surfaces that are exposed to the loading apparatus has an important effect on the compressive strength of stone and similar materials. It was noted by Mr. Merrill,[36] in 1910, that the reported compressive strengths of rocks showed a remarkable increase during 60 years. He properly attributed this to greater refinements in the preparation of the ends of the specimens. However, it does not explain the aforementioned 100% increase in the average strength of concrete, since there have been no significant changes in the methods of mixing, molding, curing, or loading the standard test cylinders. Separate studies of the effect of the compound composition of Portland cement (especially the quantity of tricalcium silicate) and of the fineness of grinding show that the increase of 100% in average concrete strength from 1918 to 1940 can be fully accounted for by these factors. Failure to recognize this notable rise in the "concrete strength level" of Portland cements has been responsible for much confusion of thought, both in scientific studies of concrete mix design and in application of these principles to construction problems.

---

[56] "Lean Concrete Mixes," by E. Gruenwald, *Proceedings*, A.S.T.M., 1939, p. 810.

[57] "Limitation Order 179, Part 3033—Portland Cement," WPB, August 3, 1942; amended August 24, September 24, 1942, February 16 and March 23, 1943.

Standard Test Cylinders Represent Idealized Conditions.—The foregoing paragraphs show that any strength test of concrete is purely relative and that nothing would be gained by changes in the test method that merely lower the strength by a fixed percentage, such as lubricating the ends of the cylinders, as suggested by Mr. Woodard.

Although the average 28-day concrete strength increased 100% from 1918 to 1940, there was no commensurate increase in the design working stresses in concrete; nor should there have been. The composition and fineness of the cement largely affect the 7-day and 28-day strength of concrete, but they do not exert proportional effects on the strength at 1 year, or 5 years. The normal Portland cement in Table 10 gave a strength at three days and the high-early-strength cement at one day that was equivalent to the 28-day strength of concrete at the time the 28-day strength was arbitrarily chosen as a basis for design stresses.

The compressive strength of concrete cylinders represents idealized conditions that rarely exist in the structure. There are always questions as to whether the concrete in the structure is as carefully placed and whether it receives a curing treatment that will enable it to gain strength, even at 28 days, comparable to that of the test cylinders made under standard conditions. This fact, however, does not minimize the importance of concrete tests made in connection with building operations, since these idealized cylinders do give a measure of the potential concrete quality. Whether this potential quality is realized on the job depends on many factors, most of which are well understood by those skilled in the art. In most applications the strength of concrete must be subordinated to durability. Durability of exposed concrete is more dependent on the use of a plastic mix of a low water-cement ratio than on the early strength. The evidence indicates that the concrete that gave 2,500 lb per sq in. at 28 days in 1918 probably is as durable as the concrete that gave 5,000 lb per sq in. in 1940.

Summary.—The writer maintains that Mr. Woodard:

(1) Completely misinterpreted his briquet tests and in doing so overlooked or ignored information that had been available for nearly 50 years. This mistake of underestimating by about 67% in the true tensile strength of mortars nullifies practically everything that follows.

(2) In his conclusions on greased blotting paper between load surfaces of mortar prisms, he overlooked similar results from using lead, as determined by tests on stone in 1851; and overlooked concrete tests made in 1923 in which blotting paper alone gave the same result.

(3) Mistakenly, he has recommended modifying the standard compression test of concrete to require lubricated ends.

C. A. P. TURNER,[58] M. AM. SOC. C. E.—Illogical deductions (see heading, "Shear and Stress") presented in Mr. Woodard's paper are that:

> "* * * (*a*) in materials strained by exterior forces including shearing forces, only two kinds of stresses are set up—compressive stresses and

---

[58] Cons. Engr., Columbus, Ohio.

tensile stresses—and (*b*) shear is accompanied by and resisted by internal forces of tension and compression. In other words, there is no such thing as shearing stress or shearing strength as distinguished from compressive and tensile stresses and compressive and tensile strength."

Axial forces cause elongation: Positive if in tension, negative if in compression. The unit stress under these conditions is $s = \frac{P}{A}$. In simple elongation, rotational strains accompany elongation. These are best visualized by a strip of rubber 1 in. in width marked off in 1-in. squares. By drawing diagonal lines from corner to corner of the squares with white lead, a kind of pantagraph frame is formed by the white lines. If the strip is stretched, these diagonal lines rotate about their intersection, disclosing the angular distortion of two-dimensional displacement. These rotational actions differentiate rotational shear strain from simple elongation.

Fig. 12.—Stress-Line Analysis of a Column Supported, Centrally Loaded, Flat Slab

Pure shear is found in the torsion of the shaft or the twist in a square flat plate under load supported on four sides, or in the case of continuous plate supported by spaced columns. Fig. 12 represents a stress-line analysis of the latter type of plate, and the traces of the spiral right and left shears on top and bottom surfaces are presented in the diagram. The coordinates of these shears are the planes of zero shear and greatest vertical shear and of zero shear and greatest twist. These shears fix the contours of curvature under load by their intersections. The contours are principal stresses at the middepth of the plate. The twisting shears which develop the contours make variable angles with the principal strain far different from 45° as given by the author. Warping of the plate generates twisting couples about the axis of x, y, and z. The sign of the twisting couples changes at the point of contraflexure and at the principal planes.[59]

Shears and Principal Stresses in Beam Action.—When a load is placed on a simply supported beam, the beam bends down under the load. The top fibers are shortened and the bottom fibers are stretched, causing a trapezoidal distortion on the vertical face of the beam. The reaction of these positive and negative deformations causes shearing stresses in the material as illustrated by the deportment of two planks of the same length, one on top of the other, with the ends in vertical planes. As the planks bend under the load, the lower corners of the upper plank slide by the upper corners of the lower plank; and, when arranged in this way, the combined stiffness and load capacity is that of two planks. If, instead of allowing the planks to slide one upon the other, they are glued together, the strength is then equal to that of four single planks and the stiffness is increased to that of eight single planks, sliding the one on the other.

The stress brought on the glue is a shearing stress, and its relative intensity at any point is proportional to the amount of sliding that would occur were the planks not so glued together. This shear causes rhombic distortion, which, in a simply-supported beam, increases from zero at the center to a maximum at the end and, in a restrained beam, increases from the center to the point of inflection, decreasing from that point to zero at the support.

The vertical cross section at midspan is the critical section resisting horizontal elongation of bending, whereas the horizontal longitudinal cross section at middepth resists the horizontal shearing stress. Because the latter cross section is far greater in area than the former, the deflection from the shear strain to which it is subjected is so small in a rectangular section when the length is greater than twelve times the depth that it is neglected in the common or approximate theory of flexure.

The building codes of all North American cities recognize three kinds of beam failure: (1) Compression failure caused by crushing the top fibers under maximum moment; (2) tension failure caused by breaking the bottom fibers in tension; and (3) shear failure caused by combination of rhombic and trapezoidal shear strains. The latter are measured by the sharpness of curvature.

For safety, building codes provide limiting fiber stresses for tension and compression, and safeguard against shear failure by specifying fixed limits for the value of the quantity, external shear force, divided by the area of the beam at the support.

Thus, by observation, building code authors recognize shear failure in beam resistance and are a step in advance of Mr. Woodard's thesis. However, the safeguard which the building codes provide against shear failure is founded on complacent ignorance as to the locus[60] of greatest strain; also there is wide[60] divergence as to its magnitude under the same external shear, depending on the distribution of load and the restraint at the support.

---

[59] "Elasticity, Structure and Strength of Materials Used in Engineering Construction," by C. A. P. Turner, Pt. 1, pp. 286–292.

In treating nonhomogenous concrete by the same theory as homogenous material, Mr. Woodard falls into an interesting error. The neutral plane of homogenous and concrete beams is the locus of consecutive states of right shearing stress, functioning as centers of rotation for each elemental section. Incidentally, in the homogenous beam, this locus is where tension and compression balance, and principal tension and compression make angles of 45° with the plane. Otherwise, the locus is in the reinforced concrete beam,[61] because the tension of the steel at the bottom equilibrates the compression in the concrete by bond shear at the surface of the steel, instead of at the neutral plane. As a result, the states of right shearing stress as centers of rotation in the neutral plane are twisted 22.5° [61] from their position in the homogenous beam. Consequently, the principal compression and horizontal shear intersect the neutral plane at 22.5°, and the curve of vertical shear and principal tension intersects that plane at 67.5°.[61] Therefore, elastic deflection of the concrete beam increases more rapidly than the load, because the neutral plane is compressed under load.

Mr. Woodard's treatment of torsion of a shaft is erroneous. The torsional moment is coordinated readily with the shear stress on a transverse section without reference to tension or compression in the material. The simplest solution is that of shear stress volume times lever,[62] which agrees with Rankine's analysis.[63]

The distribution[64] of tensile and compressive stresses and their reverse summation precludes the possibility of coordinating the torsional moment with their reactions. On a round shaft a neutral cylinder[64] (radius, 0.7071 r) is developed, on which every element is under no strain; but inside this cylinder every fiber parallel to the axis is stretched, and outside it every fiber is compressed. In the cross section all radial lines are under compression, increasing from the outer fiber to the axis; and all circular lines are under tension, which is at a maximum at the outer fiber and decreases toward the axis. Pure shear on the cross-sectional area has the same unit intensity from the axis to the surface. The spiral tensions and compressions on the surface of the shaft and each annular cylinder within intersect the cross section of pure shear at 45° only at the neutral cylinder. Their obliquity changes from 45° as radically as the twisting shears in the plate problem of Fig. 12.

The complexity of the three-dimensional strain of torsion precludes coordination of the reaction of tensile and compressive stresses with the torsional moment.

Mark W. Huggins,[65] **Esq.**—Although the writer cannot agree with the suggestions presented in this paper, he feels that its publication is certain to fulfil a useful purpose, if only by stirring up further discussion of this most important problem. The importance of this subject does not appear to be realized fully by engineers in general. The truth of this statement will be apparent to any one who studies any of the modern specifications for allowable stress. So far as the writer is aware, no specification attempts to outline any procedure which may be followed in determining safe stresses in cases of combined stress. The same stress, which is considered safe in the case of pure tension also may be used in designs in which a complex state of stress exists, provided only that the maximum principal stress does not exceed the specified limiting value for pure tension. Numerous tests, such as those published in Table 1 of the paper and in many texts on strength of materials[66] illustrate the inaccuracy of this procedure.

Any suggestion for changing the standard nomenclature of mechanics of materials is certain to lead to nothing but confusion. It has been accepted generally that the term "stress" shall apply to true forces and that "strain" shall apply to true deformation. The use of the term "stress" to define some artificial quantity, which is always proportional to strain, is not advisable as the same result might be attained just as well by setting an upper allowable limit on strain rather than on stress.

The author states that there is no need to consider "an imaginary and inexplicable thing called shear stress" in obtaining an answer to the question of how shear is resisted. He maintains that stresses are limited to tensile and compressive stresses. This hypothesis does not give a very satisfactory interpretation of the cup-cone type of failure which occurs in tension test pieces of mild steel, in which the effect of the ends would not appear to have any considerable effect on the type of failure, provided that the length of the reduced-area section is sufficiently large. The final failure is obviously of a shear type and occurs across a plane for which the normal strain is less than that in the axial direction. The initial cause of failure, in this case, is sliding along 45° planes, which produces necking. At a certain stage in the loading, the cohesive resistance of the middle part of the bar is overcome, causing a crack of the brittle type, but, at the same time, yielding by sliding continues near the surface and the final sliding fracture occurs near the boundary.[67]

A. A. Eremin,[68] **Assoc. M. Am. Soc. C. E.**—It is true, as the author states, that friction resistance at the ends of a short concrete test prism results in the appearance of an increased compressive strength in the concrete. More exact results may be obtained if the test block is made higher. Josef Fritsche[69] has shown that the compressive strength of concrete determined by a compressive test of a concrete block, with a ratio of height to width varying from 4 to 6, differs only about 20% from its true value. M. Möller[70] and later D. C. Henny,[71] M. Am. Soc. C. E., developed a method of computing the strength of concrete based on shear strength determined with a concrete test prism. The results of shear strength tests were correlated with strength tests of a concrete column and the error was found to be less than 20%.

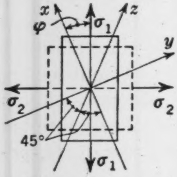

FIG. 13.—PRINCIPAL STRESSES

In the formulas for stresses and strains at an oblique section of a prism, Mr. Woodard has considered the case in which only direct stresses were applied. In practice, however, the principal stresses are generally considered along two axes. An interesting method of computing principal stresses in terms of measured strains ϵ_x, ϵ_y, and ϵ_z along three axes x, y, and z at angles of 45° was presented in 1934.[72]

In Fig. 13 the principal stresses σ_1 and σ_2 are,

$$\sigma_1 = \frac{E}{1 - \mu^2} (\epsilon_1 + \mu \, \epsilon_2) \qquad (32a)$$

$$\sigma_2 = \frac{E}{1 - \mu^2} (\epsilon_2 + \mu \, \epsilon_1) \qquad (32b)$$

and

$$\tau_{\max} = \frac{\sigma_1 - \sigma_2}{2} \qquad (32c)$$

in which

$$\epsilon_1 = \frac{\epsilon_x + \epsilon_y}{2} + \frac{\epsilon_x - \epsilon_y}{2 \cos 2 \phi} \qquad (33a)$$

$$\epsilon_2 = \frac{\epsilon_x + \epsilon_y}{2} - \frac{\epsilon_x - \epsilon_y}{2 \cos 2 \phi} \qquad (33b)$$

and

$$\tan 2 \phi = \frac{2 \, \epsilon_z - \epsilon_x - \epsilon_y}{\epsilon_x - \epsilon_y} \qquad (33c)$$

With the known modulus of elasticity E, Poisson's ratio μ, and Eqs. 32, stresses and strains at any oblique section may be computed.

In conclusion, Mr. Woodard states that Poisson's ratio in the more accurate computations must be considered. It is to be noted that, in some cases, reliable results may be obtained only if Poisson's ratio is considered.

The term "shear stress," as used by Mr. Woodard, is a misnomer. It is true that the conception of shear stress is based on assumptions that differ from those on which direct stresses are based. However, this fact entails no difficulties in computations of structural materials energy and deformations. In the more accurate computations, important consideration should be given to the limitations resulting from the assumption of straight-line variation of stresses and strains and also the neglect of plastic flow.

SILAS H. WOODARD,[73] M. AM. SOC. C. E.—Most of the critical discussions of the paper (nearly all are adverse criticisms which are not in agreement with each other) are flat rejections of the theory advanced in the paper because it does not agree with some other theory or because it does not fit the discusser's mental concept of the nature of stress. With one exception there is no citation of observed facts or recorded behavior to oppose the theory. The exception is the citation by Mr. Abrams of the relative compression tests of concrete cylinders ranging from 2 in. to 36 in. in diameter. However, the writer cannot accept those results as conclusive evidence: (1) Because the cylinders were tested with restrained ends and were not lubricated; and (2) because the material tested was concrete with coarse aggregate in the large cylinders and fine aggregate in the small cylinders. Even the mortar in concrete with aggregates 9 in. in diameter must have differed from the mortar in concrete with ½-in. maximum size of aggregate. Such differences would occur in relative workability or in water-cement ratio, or the density and workability of the entire mass would differ for different sizes of samples.

As to the nature of stress, the writer has canvassed enough engineers and physicists to learn that, although mental concepts of stresses are not all of the same pattern, his own are not entirely unique. The common practice of using the term "stress" as a ratio should not be confusing because it is still an expression of force per unit area. To be of use the computed stress should be a measure of distress. The engineer wants to know the margin of safety in his design.

For tensile stresses, the writer's concept is that, between each pair of adjacent particles of a solid, there is an elastic force which resists separation or nearer approach of the particles. So long as no other forces are acting, the distance between the particles remains constant, but other forces may be applied to separate the particles further. This applied force is resisted by the elastic force tying the particles together. If the forced separation becomes too great, the elastic resisting force reaches its limit and lets go; or, in other words, each particle passes outside the field of action of the resisting force.

When and if the physicists discover the exact nature of this elastic resisting force, the engineer will probably still rely largely on stress calculations.

The chief purpose of the paper was to emphasize the necessity for the use of Poisson's ratio in more refined stress computations. The distortion phenomenon expressed by Poisson's ratio is believed to induce stress not covered by the simple equation of external forces. The possibility of these induced stresses should not be dismissed simply by saying that they are inconceivable.

In an amorphous solid the particles are presumably arranged in a haphazard manner like marbles in a bag so that, if a force, tension or compression, is to travel from a point or particle on one side of the solid to an equal and opposite force on the other side of the solid, it must follow a zigzag course from particle to particle. At all the angle points of the zigzag line, components of force must be resisted either by external or internal force; if no external force exists, the resisting force must be internal. In the interior of the solid the components of adjacent zigzag lines, of course, will tend to balance each other, but not so at its surface. The net sum of all of the components of the principal forces or stresses is an induced stress normal to the direction of the principal stress.

---

[73] Cons. Engr., New York, N. Y.

If the principal stress is compression, the induced stress will be a tension normal to the principal stress and in that direction; the dimension of the solid will be increased following the law of Poisson's ratio; the particles in that dimension will be less closely spaced; and, if the limit of tensile strength is reached, they will separate, resulting in a tensile failure. This cannot be called inconceivable especially as brittle amorphous solids do behave that way, and the writer cannot conceive of particles being torn apart except by tensile stress.

AERATION OF SPILLWAYS

BY G. H. HICKOX,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOE W. JOHNSON, J. W. HOWE AND CLAUD C. LOMAX, JR., J. C. STEVENS, AND G. H. HICKOX.

SYNOPSIS

A method of computing the size of air vent needed for aeration of spillways, based on all of the available data, is presented in this paper. The effect of insufficient aeration on the reduction of pressure beneath the nappe and on the discharge is discussed. Formulas and diagrams for calculation of these effects are included.

INTRODUCTION

The aeration of spillways and measuring weirs has apparently not been given the attention it deserves. The direct result of insufficient aeration of overfall weirs is a reduction of pressure beneath the nappe due to the removal of air by the overfalling jet. This reduction of pressure in turn causes several undesirable secondary effects. The first is an increase of pressure difference on the weir itself. The reduction of pressure on the downstream side may increase the resultant load on the structure to the point of failure. In the case of dam A, spillway discharge flows over a gate 20 ft high. This gate was designed for a water load 20 ft over its crest, or 37,400 lb per ft of length. During tests on the aeration of this spillway, negative pressures under the nappe of 9.7 ft of water were measured. This was equivalent to an additional load of 12,100 lb per ft of length, or an increase of 32%. The significance of this increase in load becomes more apparent when it is noted that this was by no means the maximum pressure reduction that could have been obtained by closing the aeration vents completely. In this particular case, it represented the maximum extra load which it was thought the gate could support with safety.

The second effect is a change in the appearance of the nappe. Because the difference in pressure acts across the nappe itself, the nappe is depressed below its normal position. In the case of large spillways, the upper surface becomes ridged in the direction of flow and begins to entrain air instead of

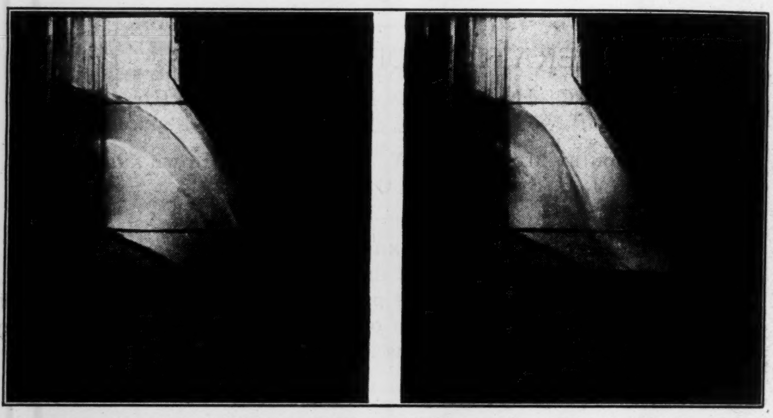
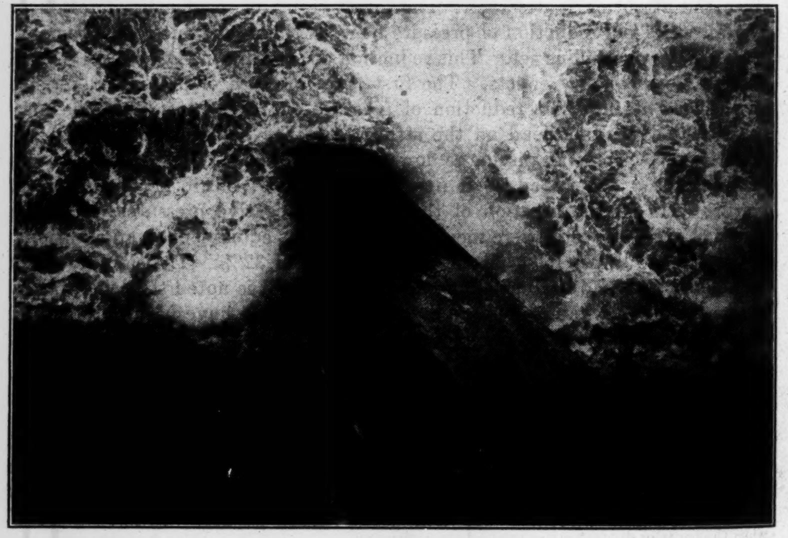
[1] Senior Hydr. Engr., TVA Hydraulic Laboratory, Norris, Tenn.

being smooth as for normal flow conditions. For thin nappes and considerable pressure reduction, the nappe may break, allowing air to pass through it. As soon as this occurs, the nappe springs back to its normal position and the process of air exhaustion and breaking of the nappe is repeated. Depression of the nappe because of insufficient aeration is illustrated on a small scale model by Figs. 1(a) and 1(b) and for a large spillway by Fig. 1(c).



a) Discharge Over Model (1 : 25 Scale) of Lower Gate Leaf; Full (or Complete) Aeration

(b) Discharge Over Model (1 : 25 Scale) of Lower Gate Leaf; No Aeration



(c) Prototype: Gate at Left Aerated; 2-Ft Vacuum Under Nappe at Right

Fig. 1.—Depression of the Nappe Because of Insufficient Aeration, Dam A

A third result of the reduction of pressure beneath the nappe is an increase in the pressure difference causing flow over the weir, and a corresponding increase in the discharge coefficient. For a given head, the discharge is increased. If the discharge is fixed, the measured head is reduced.

Reduction of pressure beneath a spillway nappe is also undesirable from the standpoint of the performance of hydraulic models. Fig. 1(*b*) illustrates a pressure reduction of about 1.5 ft in a 1 : 25 scale model, or 37 ft in the prototype; a result which is clearly not possible. In some cases, the performance of a stilling basin may be completely altered because of the difference in the manner in which the spillway discharge enters it, due entirely to lack of aeration of the nappe.

Where a weir is to be used for measuring purposes, lack of aeration results in an increased discharge, and sometimes, as mentioned, a fluctuation or pulsation of the nappe, which may be very objectionable.

There is a definite need for information on the effect of lack of aeration of weirs. Such information is necessary (*a*) to prevent excessive loads on spillway gates; (*b*) to insure the reliability of model tests, with respect both to the pressure reduction to be expected in the prototype, and the performance of the stilling basin; and (*c*) to provide a criterion for the necessary aeration of measuring weirs.

NOMENCLATURE

The letter symbols used in this paper are defined where they first appear in the paper and are assembled for reference in the Appendix.

EXPERIMENTAL DATA

The problem of aeration became important with the construction of dam A. There are twenty-two spillway gates at this dam, each built in two sections 20 ft by 40 ft, operating in the same vertical plane. Discharge is regulated by first lifting the upper leaves and allowing the water to flow over the tops of the lower leaves. The lower leaves are not raised until after all the upper leaves are open. The design of the piers is such that self-aeration is impossible and aeration vents are necessary. The same gate design and similar operation were provided for dams B, C, and D. At dam D, the problem was complicated by the fact that, under certain conditions, water might discharge beneath the lower gates as well as above them. A knowledge of the size of aeration vents required was necessary in designing these projects,

[a] Values of q_a in Table 1(*a*) are in millionths. [b] Feet of water.

[c] These values of H_e were not measured. They were computed with the assistance of the curve in Fig. 9.

and laboratory tests were undertaken to supply the needed information. Fig. 2 is a schematic diagram showing the dimensions which were measured in the various experimental setups.

The only previous experimental data which could be found were those referred to by J. W. Johnson,[2] Assoc. M. Am. Soc. C. E. His experiments were performed on a weir 1 ft long under heads varying from 0.171 to 0.305 ft (see Table 1(*a*)). In tests 1 to 76 of Table 1(*a*), air was allowed to recirculate beneath the nappe, giving rather uncertain values of q_a. In tests 83 to 106, recirculation was prevented by a sloping baffle beneath the nappe. Mr.

Johnson obtained an expression for the quantity of air required per foot length of weir as

$$q_a = 0.0019\,(q_o)^{2.1} \quad \ldots\ldots (1)$$

—for heads less than 0.4 ft; and

$$q_a = 0.0096\,(q_o)^{2.1} \quad \ldots\ldots (2)$$

—for heads greater than 0.4 ft. In view of the variation of the coefficient at low heads, and the dimensional nature of the equations, it was thought advisable to conduct additional experiments before applying these equations to gates having crests 40 ft long and operating under heads of 20 ft.

[a] In millionths of a cubic foot per second. [b] Feet of water.

Accordingly, the laboratory conducted a series of tests on a larger weir to extend the range of Mr. Johnson's data. An 8-ft suppressed weir available at the laboratory was fitted with an arrangement for measuring the air required. Fig. 3 illustrates the apparatus. Full aeration was obtained by two 1.5-in. pipes, placed one at each end of the weir, as shown. These pipes caused two openings about 2 in. wide the entire height of the nappe. When full aeration was not desired, the pipes were removed and the air admitted under the nappe was measured by orifices 0.25 in., 0.5 in., and 2 in. in diameter mounted on a box about 1 ft square. The air was conducted under the nappe through a duct placed in the slot supporting the weir bulkhead. The differential pressure on the orifice was measured with a tilting water manometer. The pressure under the nappe was not measured directly but was calculated as the pressure drop across the measuring orifice plus the pressure drop through the connecting duct. The correction was negligible for the smaller orifices and was not large for the 2-in. orifice. A sloping baffle was provided below the weir to eliminate the recirculation of air which Mr. Johnson found in his experiments. The head on the weir varied from 0.258 ft to 1.097 ft. The tailwater level varied through the approximate range indicated in the figure. Discharges were measured by allowing the water to flow over the weir with the nappe completely ventilated. An accurate volumetric calibration for this condition of flow was available. The air requirement for this discharge was then measured with each of the orifices. A few runs were made with no air at all supplied under the nappe. Air and water temperatures were recorded. The data are given in Table 1(*b*).

In connection with the aeration requirements of dam D, additional tests were made to determine the effect of discharge beneath the gate as well as over it. A 2-ft weir, on which the head could be raised to 1.4 ft, was used for these tests. To prevent the back circulation of air drawn beneath the nappe, the lower face of the bulkhead was sloped so that the nappe fell on it. Three gates, 0.5 ft, 1.0 ft, and 2.0 ft high, were used with openings beneath them of 0, 0.1, 0.5, and 1.0 ft. The head over the crest varied from 0.095 ft to 1.409 ft. The air required was measured in the same way as that for the tests on the 8-ft weir. Discharges were measured by the calibrated 8-ft weir. Fig.

[a] In millionths of a cubic foot per second. [b] Feet of water.

In addition to the laboratory tests, it was possible to make observations of the actual air requirement of the dam A spillway. Fig. 5 shows the method of aerating this spillway. Each bay received air through two 16-in. pipes which terminated at their upper ends in a chamber at the downstream face of the pier. Piezometers were provided so that the pressure under the nappe could be measured. The air supplied was measured by placing orifice plates over the entrances to the chambers at each end of the bay and sealing the pipes aerating the adjacent bays. A pressure connection on the orifice plate permitted the rate of air flow to be calculated from the pressure difference across the orifice. Fig. 6 shows the orifice plate and pressure connection. All pressures were measured by means of water or mercury manometers located on the spillway deck. The quantity of air required and the reduction of pressure beneath the nappe were varied for a given head on the gate crest by changing the orifice plates. The crest of the weir was 40 ft long, the heads varied from 11.59 ft to 19.04 ft, and the reduction of pressure beneath the nappe from 0.53 ft to 9.68 ft. Table 1(*c*) gives the data.

ANALYSIS OF TEST DATA

Air Required for Aeration.—The quantity of air supplied beneath the nappe in all of the experiments except Mr. Johnson's, both in the laboratory and in the field, was measured by sharp-edged circular orifices and calculated by the hydraulic formula modified by the coefficient of Bean, Benesh, and Buckingham. For the case of discharge through an orifice from the free atmosphere, the equation reduces to

$$Q_a = (0.597 - 0.00844\,h) \times A \sqrt{2\,g\,h\,\frac{w_w}{w_a}} \ldots\ldots (3)$$

in which: Q_a is the rate of air supply in cubic feet per second at atmospheric pressure; h = head on the orifice in feet of water; A = area; g = acceleration due to gravity; w_a = unit weight of air in pounds per cubic foot; w_w = unit weight of water; and B = length of weir crest, in feet.

The rate of air discharge in Mr. Johnson's experiments (Table 1(*a*)) was measured by means of a capillary tube.

[a] In millionths of a cubic foot per second. [b] Feet of water.

The wide range of the variables involved in the experiments made it desirable to use a dimensionless form of representation. It was found that the relationship between pressure reduction, air required, and head over the top of the gate could be represented by plotting

$$\alpha = \frac{(q_a)^{0.5}}{g^{0.25}\,p^{0.25}\,H_o} \ldots\ldots\ldots\ldots\ldots\ldots (4a)$$

against

$$\beta = \frac{(q_a)^{0.5}}{g^{0.25}\,p^{1.25}} \ldots\ldots\ldots\ldots\ldots\ldots (4b)$$

in which: q_a = the rate of air supply per foot length of crest, $\frac{Q_a}{B}$; p = reduction of pressure beneath nappe, in feet of water; and H_o = head over the top of the gate, corresponding to the pressure reduction p. The length of crest was eliminated by assuming that each foot of length of overfalling nappe was independent of every other foot of length and that the total air required was proportional to the length. Fig. 7 is a plot of these variables for all tests in which discharge occurred only over the top of the gate. It will be seen that the results obtained with the different experimental arrangements agree with each other within the limits of accuracy of the tests. It is particularly noticeable that Mr. Johnson's data on a 1-ft weir fall on both sides of the points obtained on the dam A spillway. The effect of the height of the overfalling nappe on the air required was investigated by comparing the tests made with different heights of gate on the 2-ft weir. The tailwater elevation depended on the discharge, but since the channel was wide, this did not vary greatly. Fig. 8 is a plot of $\frac{(q_a)^{0.5}}{g^{0.25}\,p^{0.25}\,H_o}$ against $\frac{(q_a)^{0.5}}{g^{0.25}\,p^{1.25}}$ for these data. No definite trend can be established. Any variation due to the height of the nappe is masked by the uncertainties of the experimental data.

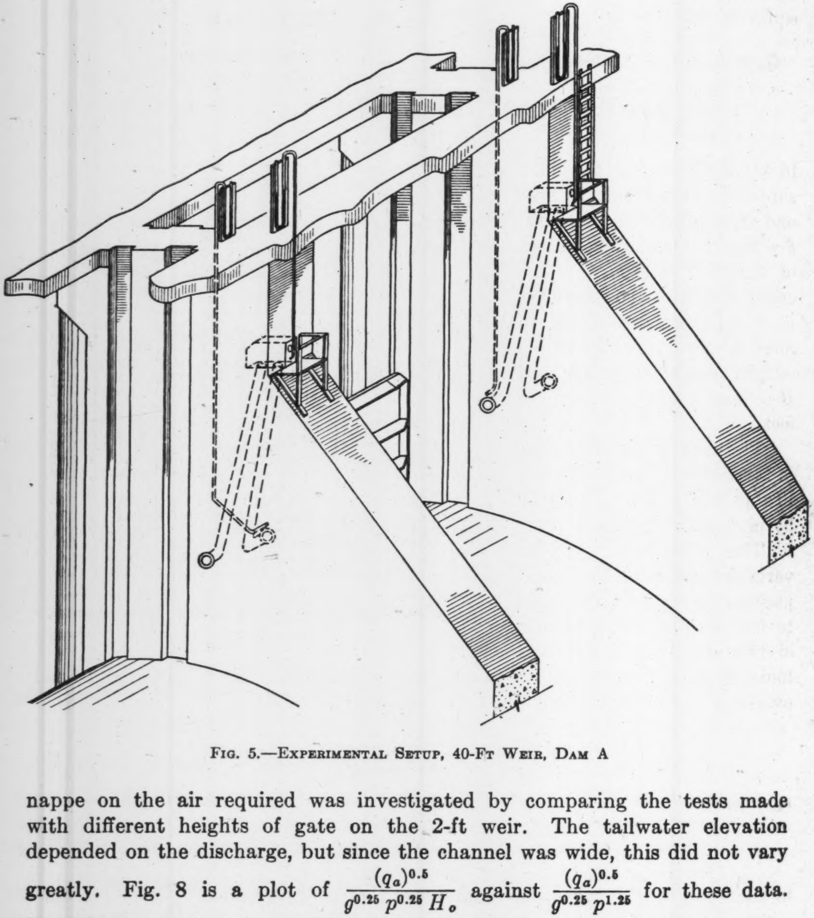

FIG. 5.—EXPERIMENTAL SETUP, 40-FT WEIR, DAM A

It was found that the results for the tests made with discharge beneath the gate could be represented satisfactorily by the dimensionless groups used for discharge over the gate, as long as the ratio of discharge beneath the gate to discharge over the gate remained constant. Since it was difficult to measure the two discharges separately with the experimental setup used and since such separation would be practically impossible in field installations, the ratio of discharges was represented as follows: Let Q_o and Q_u be the discharge over and beneath the gate, respectively; then:

$$Q_u = C_u\, B\, y\, \sqrt{H_u} \,..\, (5a)$$

and

$$Q_o = C_o\, B\, (H_o)^{1.5} \,...\, (5b)$$

and the ratio of discharges is

$$\zeta' = \frac{Q_u}{Q_o} = \frac{C_u\, y\, \sqrt{H_u}}{C_o\, (H_o)^{1.5}} \,..\, (6)$$

If it may be assumed that C_u and C_o are constant, the ratio may be expressed as

$$\zeta = \frac{y\, \sqrt{H_u}}{(H_o)^{1.5}} \,.....\, (7)$$

This form has the advantage of being composed of terms which are easily measured.

The ratio ζ was calculated for each test in which flow beneath the gate occurred (see Tables 3 to 5). All the data were then arranged in groups covering small ranges of ζ, as follows:

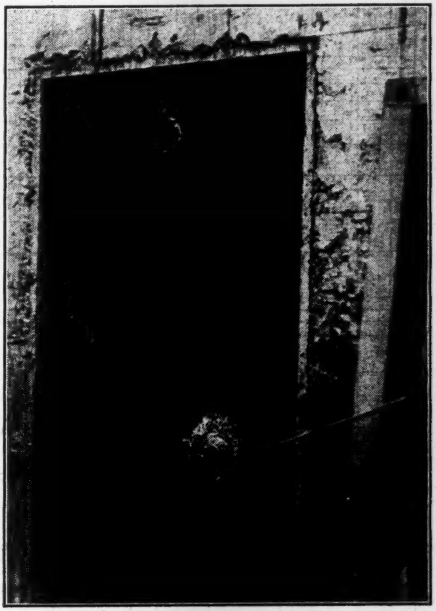

FIG. 6.—ORIFICE PLATE AND PRESSURE CONNECTION FOR MEASURING AIR SUPPLY AT DAM A

Range of ζ	Average ζ	No. of tests
0	0	93
0-0.4	0.17	20
0.4-1.2	0.81	24
1.2-2.3	1.79	24
2.3-3.3	2.81	10
3.3-4.5	4.0	6
4.5-5.5	5.1	5
>5.5	....	9

The data were plotted on separate sheets, using the groups $\frac{(q_a)^{0.5}}{g^{0.25}\, p^{0.25}\, H_o}$ and $\frac{(q_a)^{0.5}}{g^{0.25}\, p^{1.25}}$ as ordinates and abscissas, respectively, and the best straight line was drawn through each group. It was found that slight adjustments would make all the lines parallel with a slope of 0.45. Accordingly, the equa-

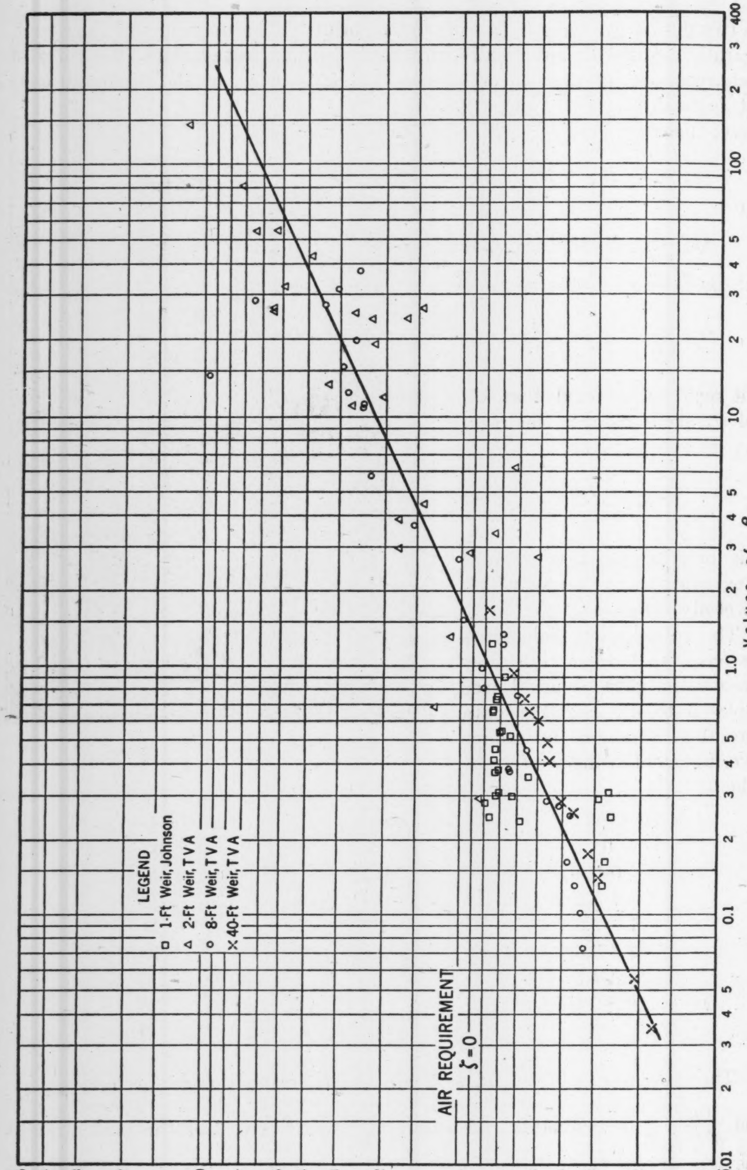

Fig. 7.—Effect of Weirs for ζ = 0

tion of each line could be written

$$\frac{(q_a)^{0.5}}{g^{0.25}\, p^{0.25}\, H_o} = C \left[\frac{(q_a)^{0.5}}{g^{0.25}\, p^{1.25}}\right]^{0.45} \qquad \text{.................. (8)}$$

in which C is a constant for each value of ζ. Fig. 9 shows the relation between C and ζ. The value of C increases rapidly for small values of ζ, but apparently reaches a maximum value of 0.225 at $\zeta = 2.5$. Further increase in ζ does not increase C.

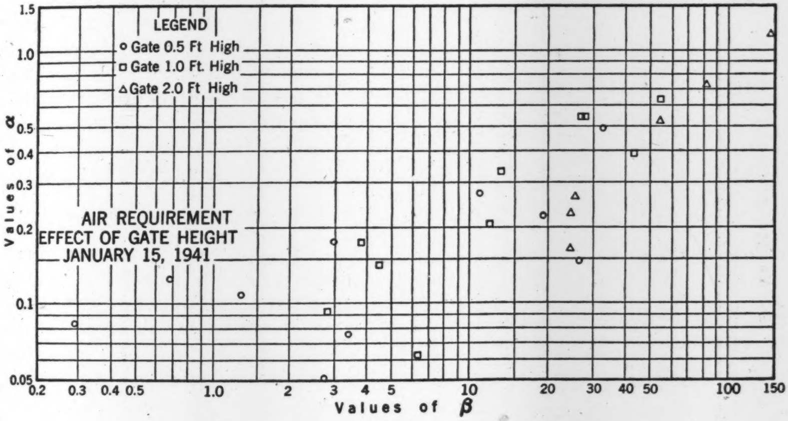

FIG. 8.—EFFECT OF GATE HEIGHT ON THE AERATION OF WEIRS

Eq. 8 may be solved for q_a:

$$q_a = \frac{(C\, H_o)^{3.64}\, g^{0.5}}{p^{1.14}} \qquad \text{.................. (9)}$$

Eq. 9 gives the quantity of air required per foot of length for a weir operating under specified conditions of gate opening, head, and pressure reduction beneath the nappe.

Effect of Pressure Reduction on Discharge.—The reduction of pressure beneath the nappe increases the effective head on the weir and causes the discharge for a given head to be greater than would be the case if the nappe were fully aerated. Similarly, for a given discharge, reduction in pressure decreases the measured head on the weir. The experimental data described in the preceding section provided a means of evaluating this effect. Fig. 10 is a plot of the ratios p/H_o and H_o/H'. A smooth curve has been drawn through the points.

The increase in discharge for a given head, caused by reduction of pressure beneath the nappe, can be calculated from these data. Suppose that the weir discharge at H is Q and at a slightly larger head H' is Q'. By reducing the pressure under the nappe, it would be possible to produce the discharge Q' with the head H. The increase of discharge at head H is then $Q' - Q$ and the ratio of this increase to the fully aerated discharge at head H is $\frac{Q' - Q}{Q}$. If the discharge coefficient of the weir is assumed to be constant, the ratio of increase in discharge may be written as $\frac{(H')^{1.5} - H^{1.5}}{H^{1.5}}$ or $\left(\frac{H'}{H}\right)^{1.5} - 1$. Fig. 10 gives the value of H_o/H' for any value of p/H_o. With this information it is a simple matter to calculate the increase in discharge. Fig. 10 also shows the percentage increase of discharge in terms of p/H_o. This curve is particularly useful in evaluating the effect of insufficient aeration on discharge where it is not possible to aerate the weir properly.

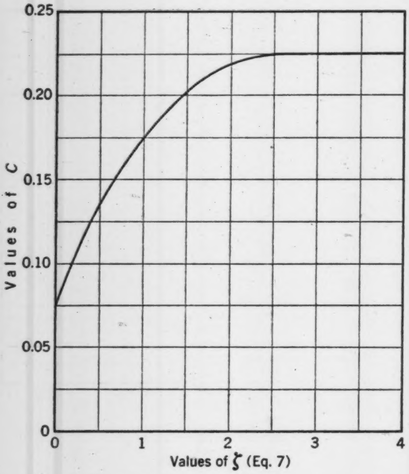

FIG. 9.—RELATION BETWEEN C AND ζ

APPLICATION OF RESULTS

Calculation of Aeration Vent Required.—Eq. 9 and Fig. 9 give sufficient information to determine the quantity of air required to maintain the pressure reduction beneath the nappe at any desired value. As an example, consider a spillway gate 40 ft long with water discharging over it under a head of 15 ft. Since there is no discharge beneath the gate, $\zeta = 0$. Fig. 9 shows that C for this condition is 0.077. It will be assumed that it is desired to limit the pressure reduction beneath the nappe to a maximum of 2 ft. Eq. 9 gives the air requirement for these conditions as $q_a = \frac{(0.077 \times 15)^{3.64} g^{0.5}}{2^{1.14}}$ = 4.35 cu ft per sec per ft of length of weir or 174 cu ft per sec for the 40-ft length of gate.

The vent diameter required to carry this amount of air may be computed by the use of the ordinary hydraulic equations. The effect on the area caused by neglecting compressibility is about 4% for a pressure reduction of 5 ft. In terms of diameter of vent, this difference is negligible. In calculating the flow of air, the effective head must be stated in terms of feet of air rather than feet of water. The value of p as given must be multiplied by the ratio of the unit weight of water to that of air. For air at 70° F, this ratio is approximately 830. In the example given, suppose that the most convenient method of venting is by the use of a pipe 30 ft long, with two right-angle bends and a sharp-cornered entrance. It is obvious that the total pressure drop through the vent pipe is equal to the pressure reduction beneath the nappe. A preliminary calculation of the pressure drop may be made with an assumed pipe diameter, say, 1 ft, and an air temperature of 70°. For these conditions, the

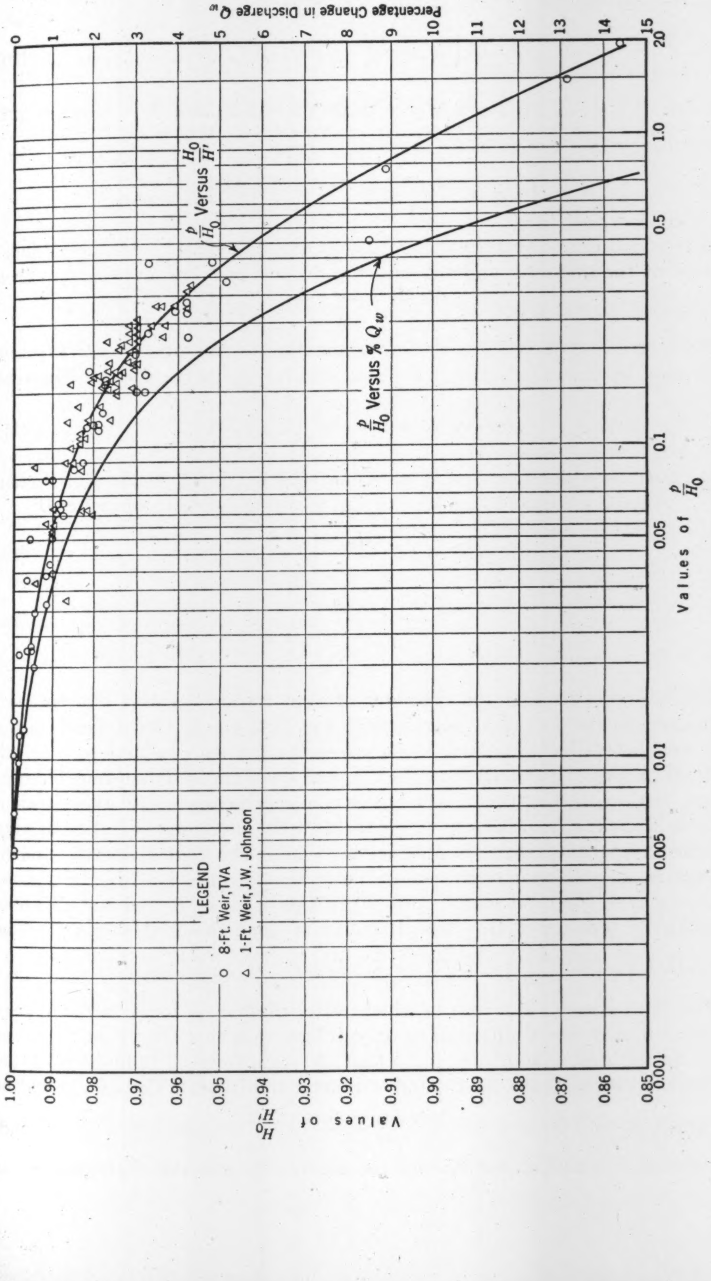

FIG. 10.—RELATION BETWEEN $\frac{p}{H_0}$ AND $\frac{H_0}{H'}$

pressure drop for the amount of air required is

$$p = \frac{w_a}{w_w}\left(C_e + \frac{f\,L}{D} + 2\,C_b + 1\right)\frac{V^2}{2\,g} \tag{10}$$

in which: $\frac{w_a}{w_w} = \frac{1}{830}$; $C_e = 0.5$; $f = 0.02$; $C_b = 0.5$; and $V = \frac{174}{0.785} = 222.$ Substituting these values in Eq. 10,

$$p = \frac{1}{830}\left(0.5 + \frac{0.02 \times 30}{1} + 1 + 1\right)\frac{222^2}{2\,g} = 2.85 \text{ ft.}$$

Since the friction loss coefficient is relatively small, it may be considered independent of the diameter and the pressure drop is proportional to D^4. Then the required diameter is $D = \left(\frac{2.85}{2}\right)^{0.25} \times 1 = 1.09$ ft.

There is a relation between the vent diameter and the other variable factors which may be found by writing the equation for discharge through the vent

$$Q_a = q_a\,B = \frac{C'\,\pi\,D^2}{4}\sqrt{2\,g\,p\,\frac{w_w}{w_a}} \tag{11}$$

in which C' is a coefficient that combines the entrance, head, and friction losses. Solving for q_a and equating to Eq. 9, it is possible to solve for D:

$$D = C''\,\frac{(H_o)^{1.82}\,B^{0.50}}{p^{0.82}} \tag{12}$$

in which

$$C'' = \frac{2\,C^{1.82}}{\sqrt{C'\,\pi}\,\sqrt[4]{2\,\frac{w_w}{w_a}}} \tag{13}$$

Eq. 12 indicates that the diameter of vent required varies directly with the square root of the crest length, with the 1.82 power of the head on the crest, and inversely with the 0.82 power of the pressure reduction. (It will be noted in Eqs. 11 and 12 that since q_a has been given dimensions of cubic feet per second, B must be considered as dimensionless.) With this relationship established, it is necessary to go through the foregoing calculations only once for any particular weir or gate installation. The vent diameter required for any reasonable variations can be determined from Eq. 12. In the example, suppose the crest length were 50 ft, the head 20 ft, and the allowable reduction of pressure 3 ft. The diameter of vent required would then be $D = 1.09\left(\frac{20}{15}\right)^{1.82}\left(\frac{50}{40}\right)^{0.50}\left(\frac{2}{3}\right)^{0.82} = 1.47$ ft.

The procedure for the case in which water discharges beneath the gate as well as over it is very similar. The only difference is that the value of ζ is not zero. In the first example, suppose that the gate were 20 ft high and lifted 6 ft, the elevation of the headwater remaining the same. Then H_o would be 9 ft, y would be 6 ft, and $\zeta = \frac{y\,\sqrt{H_u}}{(H_o)^{1.5}} = \frac{6 \times \sqrt{32}}{9^{1.5}} = 1.26$. The corresponding value of C from Fig. 8 is 0.190. Eq. 9 gives the amount of air required as

$q_a = \frac{(0.190 \times 9)^{3.64} g^{0.5}}{2^{1.14}}$ = 18.1 cu ft per sec per ft of length or 724 cu ft per sec for the entire gate. If the same method of venting is used as in the first example, the vent diameter required is 2.17 ft. This condition should always be investigated where there is a possibility of its existence. The reduction of pressure which would be developed with the 1.09-ft vent can be found by rewriting Eq. 12 in terms of pressure

$$p = C''' \frac{H^{2.22} B^{0.61}}{D^{1.22}} \qquad (14)$$

from which $p = 2\left(\frac{2.17}{1.09}\right)^{1.22}$ = 4.63 ft of water, which is more than double the allowable reduction of 2 ft.

Care should be taken to see that Eqs. 12 and 14 are used only in cases where the value of C is constant as this is a necessary condition of their derivation.

Calculation of Discharge for Incomplete Aeration.—Referring again to the first example, it is desired to know the actual discharge over the gate when the pressure reduction beneath the nappe is 2 ft of water. It may be known, from model tests, for example, that the discharge for a fully aerated nappe is 8,000 cu ft per sec. The ratio $\frac{p}{H_o} = \frac{2}{15} = 0.133$. Fig. 10 shows that the corresponding increase in discharge is 2%, or 160 cu ft per sec, making the total discharge 8,160 cu ft per sec for these conditions.

The data available are not sufficient to determine the increase in discharge when water is flowing both over and beneath the gate.

Conclusions

All of the available data on aeration of spillways have been collected and analyzed for the purpose of providing a workable criterion for the size of aeration vents required. The dimensionless groups selected do not reflect the effect of height of fall or angle of impact of overfalling nappe on spillway face or tailwater, although these factors would seem to be involved. Nevertheless, the agreement between small spillways 1 ft long at a head of 0.4 ft and a large spillway 40 ft long at a head of 19 ft is close enough for design purposes.

An interesting and useful by-product of the investigation was the effect of reduction of pressure beneath the nappe on the relation between head and discharge.

It is hoped that the discussion will bring out other data that will either support or disprove the results presented.

APPENDIX

Notation

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Hydraulics, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:[3]

A = area, in square feet;
B = length of weir crest, in feet;
C = (see Eq. 8);
C_b = coefficient of bend loss;
C_e = coefficient of entrance loss;
C_o = discharge coefficient for flow over the gate;
C_u = discharge coefficient for flow under the gate;
C' = coefficient combining the entrance, head, and friction losses;
C'' = (see Eq. 13);
C''' = (see Eq. 14);
D = diameter of pipe, in feet;
f = coefficient of pipe friction in the Fanning formula;
g = acceleration of gravity, in feet per second^2;
H = head on the weir, in feet;
H_o = head over the top of the gate corresponding to a pressure reduction p, in feet;
H_u = head on the center of the opening below the gate, corresponding to a pressure reduction p, in feet;
H' = head over the top of the gate for full aeration, in feet;
h = head on the orifice, in feet of water;
L = length of pipe, in feet;
p = reduction of pressure beneath the nappe, in feet of water;
Q = discharge over a fully aerated weir at head H, in cubic feet per second;
Q_a = rate of air supply, in cubic feet per second, at atmospheric pressure;
Q_o = discharge over the top of the gate, in cubic feet per second;
Q_u = discharge beneath the gate, in cubic feet per second;
Q' = discharge over a fully aerated weir at the head H', in cubic feet per second;
q = discharge per unit width of weir, in cubic feet per second;
q_a = rate of air supply per foot length of crest, Q_a/B, in cubic feet per second;
q_o = discharge over the top of the gate per foot length of crest, Q_o/B, in cubic feet per second;
V = mean velocity, in feet per second;
w = weight per unit volume:
    w_a = unit weight of air, in pounds per cubic foot;
    w_w = unit weight of water, in pounds per cubic foot;
y = height of the opening below the gate, in feet;
α = a dimensionless group defined by Eq. 4*a*;
β = a dimensionless group defined by Eq. 4*b*;
ζ = a dimensionless ratio, $\frac{y\sqrt{H_u}}{(H_o)^{1.5}}$: ζ' = ratio of discharges Q_u/Q_o.

[3] ASA—Z10.2—1942.

DISCUSSION

Joe W. Johnson,[4] **Assoc. M. Am. Soc. C. E.**—Air is withdrawn from the underside of a nappe by the falling sheet acting as a friction pump. The air withdrawn is replaced from two sources: (1) The air that flows through air vents to the space under the nappe, and (2) that which, upon being drawn into the downstream pool by both sides of the falling sheet, strikes the channel bottom and circulates back and upward to the space under the nappe. The observations[5] of the writer on a 1-ft weir indicated that the quantity of air withdrawn was proportional to the velocity of the falling sheet or, within certain limits, to the discharge. The only effect of the position of the downstream water level is the variation of the quantity of air circulated. If a deflector is placed near the underside of the nappe, as shown by Mr. Hickox in Fig. 3(*b*) and by the writer in Fig. 11, air is prevented from circulating backward into the space under the nappe. Therefore, all air that is finally withdrawn must first enter through the air vents. A direct measure of the power of the falling sheet to withdraw air is thus determined by the insertion of a deflector. The data from the writer's experiments on a 1-ft weir with heads never exceeding 0.4 ft are shown in Table 1(*a*), tests 76 and 83 to 106. A plot of these data is shown in Fig. 11 from which Eq. 1 is obtained.

In passing, it may be well to discuss briefly the reason for the differences between Eqs. 1 and 2. Upon examination of these equations, the reader is inclined to conclude that a "break" occurs in the relationship between q_a and q_o at a head of 0.4 ft. Actually, Eq. 1 was based on only the laboratory experiments plotted in Fig. 11, and Eq. 2 was based on both the laboratory experiments and some data on a large weir in the San Joaquin Valley. The extensive data collected since the writer's experiments have permitted a conclusive analysis of the problem of partial aeration as well as of the design of air vents. Thus, by utilizing all available data from both the laboratory and the field, Mr. Hickox has obtained excellent correlation between the various observations by means of dimensionless groups. In view of the wide range of conditions covered by this analysis, the author's procedure for designing air vents should be considered as superseding all previous methods.

To show the effect of different positions of the downstream channel bed and the effect of different depths of pools, several experiments were performed where conditions existed as shown in Figs. 11(*b*) and 11(*c*). The quantity of air, as indicated by the various curves, is that delivered beneath the nappe through the air vents. Fig. 11 shows that, for a particular position of the downstream channel bed, the volume of air taken in through the vents increases as the depth of pool decreases. In other words, the volume of air circulated decreases as the depth of pool is decreased since the volume drawn outward is the same for all depths.

[5] "The Aeration of Sharp-Crested Weirs," by Joe W. Johnson, a thesis presented to the Univ. of California, Berkeley, Calif., in May, 1934, in partial fulfilment of the requirements for the degree of Master of Science in Engineering (unpublished).

When a deflector is placed to prevent air from entering into the space under the nappe by any method except through the vents, the quantity of air withdrawn is given by Eq. 9, which is based on all available laboratory and field data. However, if air is allowed also to enter the underside of the nappe by circulation, less air is taken in through the vents and the relationship between flow of air through the vents and the other variables is different from that shown by Eq. 9. The quantity of air flowing through the vents depends on

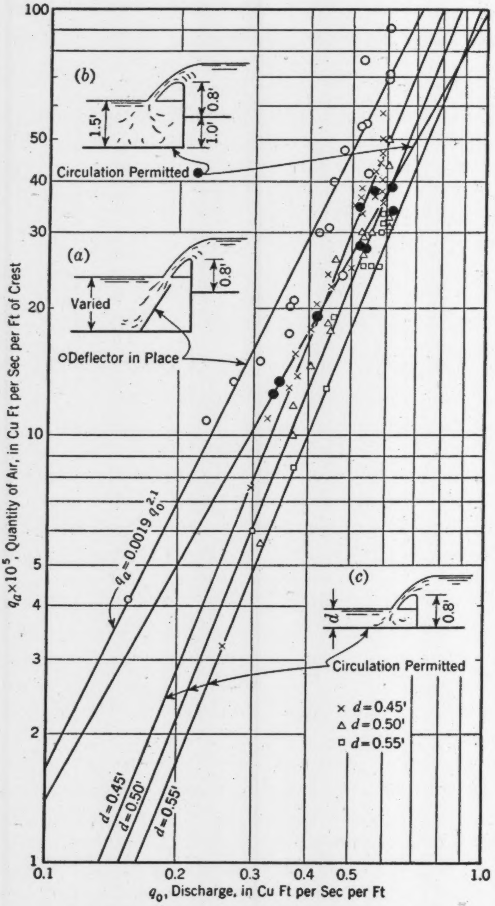

FIG. 11.—RELATION BETWEEN DISCHARGE AND QUANTITY OF AIR DRAWN THROUGH INLETS TO THE UNDERSIDE OF THE NAPPE OF A SHARP-CRESTED WEIR WITH VARIOUS CONDITIONS OF BOTTOM POSITION AND DEPTH IN THE DOWNSTREAM POOL

the position of the bed and the depth of the downstream pool with respect to the weir crest.

A reduction in the pressure under the nappe depresses the nappe inward and reduces the head on the weir by a certain amount. The effect of depressing the nappe generally expands the cross-section area of the nappe at the crest and thus increases the discharge by making the head more effective. The net result is to increase the weir coefficient.[6] For example, Fig. 12 shows the variation of the weir coefficient with the degree of aeration for the 1-ft weir tested by the writer. For a certain head the effect of preventing free access of air to the underside of the nappe gives a discharge greater than that obtained by complete aeration. A maximum increase in discharge of 23% resulted with an "adhering" nappe, and the "wetted underneath" and "depressed" conditions gave increases of 18% and 6%, respectively.

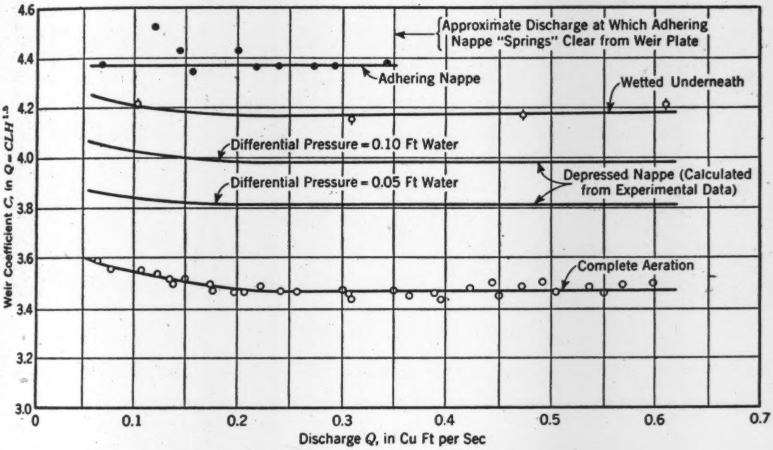

FIG. 12.—WEIR COEFFICIENT FOR VARIOUS CONDITIONS OF AERATION

J. W. HOWE,[7] ASSOC. M. AM. SOC. C. E., AND CLAUD C. LOMAX, JR.,[8] JUN. AM. SOC. C. E.—A practical problem which long has been neglected is comprehensively discussed in this paper. Also, the serious overload that can be produced by insufficient aeration of a gate or spillway is emphasized. The material presented should be welcome indeed to designers who must provide aeration ports in hydraulic structures.

Several years ago a rectangular weir in the laboratory of the Iowa Institute of Hydraulic Research at Iowa City was found to have an inconsistent head-discharge relation. Edward Soucek, Assoc. M. Am. Soc. C. E., believed this behavior was due to insufficient aeration, and later proved his point by enlarging the aeration ports, thereby obtaining a consistent relation between head and discharge. Remembering this incident, the writers undertook an investigation of the effect of insufficient aeration upon the discharge over a weir.[9]

Arrangements were made to measure, by means of small orifices, the air requirements of a 2.5-ft rectangular suppressed weir 1.67 ft high whose discharge could be determined from previously calibrated supply sources. No attempt was made to prevent the return of air to the underside of the nappe as it discharged freely into the tailwater. This procedure was in contrast to that followed by Mr. Hickox who did not allow air to return to the underside of the nappe. The apparatus permitted a variation of discharge between 0.52 and 3.60 cu ft per sec per foot of crest, a height of fall between 0.07 and 1.57 ft, and pressure reductions p up to 0.65 ft of water. Aeration was varied from none to complete by interchanging entrance orifices of different sizes on the aeration port (see box near center of Fig. 13). The pressure reduction was limited either by the complete evacuation of the air or by air breaking through the nappe.

---

[9] "The Effect of Aeration Rates Upon the Discharge Over a Suppressed Weir," by Claud C. Lomax, Jr., a thesis presented to the State Univ. of Iowa, Iowa City, in 1942, in partial fulfilment of the requirements for the degree of Master of Science in Hydraulic Engineering.

Direct comparison of the author's and the writers' results is possible only in the relation of pressure reduction to the consequent change in head, a striking agreement existing in this respect. The writers used a relation involving $\Delta H/H'$ and p/H' rather than H_o/H' and p/H_o as used by the author. However, multiplication of p/H_o by H_o/H' gives p/H'; and $\Delta H/H'$ equals $1 - H_o/H'$. These transformations (see Tables 6 and 7) permit the comparison shown in Fig. 14. The line whose equation is

$$\frac{\Delta H}{H'} = 0.115 \left(\frac{p}{H'} \right)^{0.85} \quad \ldots (15)$$

was located on the basis of the writers' experiments rather than from the points (encircled) taken from Fig. 10.

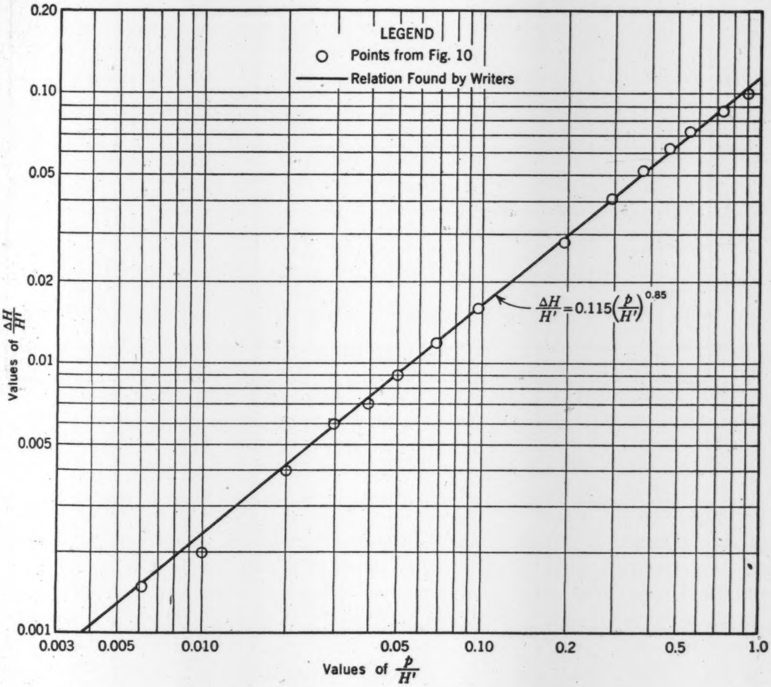

FIG. 14.—CHANGE OF HEAD WITH PRESSURE

The agreement between the two sets of data is again illustrated by Fig. 15 in which the writers' data are plotted on Fig. 10, precise agreement being evident up to $p/H_o = 0.9$. This independent evidence substantiates the author's relation between pressure reduction and discharge and emphasizes, as well, the importance of adequate aeration in the measurement of water. The highest value of p/H' observed by the writers was 0.9 which caused a change $\Delta H/H'$ of 0.105. A change of this magnitude indicates the possibility of an error in discharge computed from the observed head of approximately $3/2 \times 0.105 \times 100 = 16\%$.

Although the return of air to the underside of the nappe greatly complicates the estimation of air demand, it is commonly encountered in the use of weirs. The writers feel that such factors as the discharge, the roughness of the crest, the height of fall, the depth of tailwater, the conformation of the bed, and perhaps even the pressure reduction are involved. Some qualitative evidence of the influence of certain of these factors was found.[9] Empirical expressions relating the air discharge, the water discharge, and the height of fall were obtained, but these were not dimensionally homogeneous and depended upon the diameter of the air orifice used, making them of doubtful value in another situation. The author is reluctant to impute significance to the scattered points of Fig. 8, but it is evident that, in general, the data for the 2-ft gate

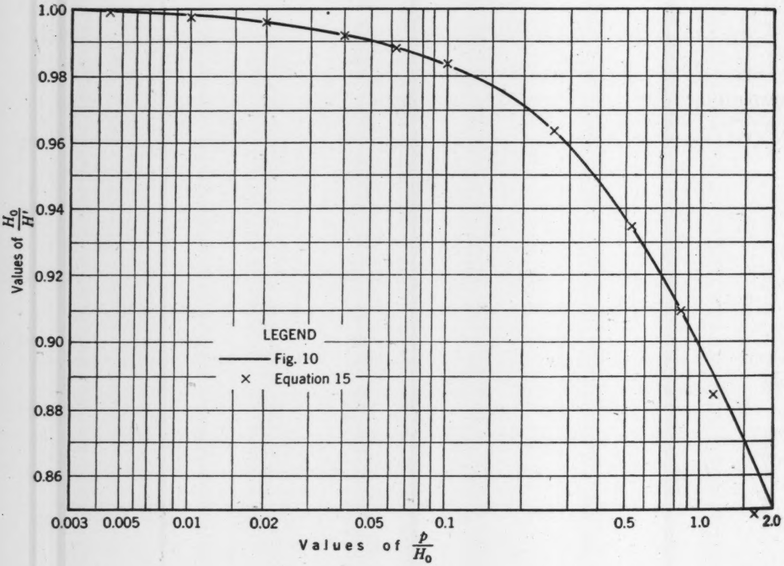

FIG. 15.

show a greater air demand than do those of the 1-ft gate with its shorter height of fall.

There is still need for considerable study of the air requirements of measuring weirs discharging naturally into the tailwater.

J. C. STEVENS,[10] M. AM. SOC. C. E.—The data and formulas presented in this paper will aid greatly not only in designing spillways but in ascertaining the flow characteristics of existing spillways. The profession's thanks are due the author for his contribution.

The author apparently assumes that it is always desirable to prevent subatmospheric pressures beneath the nappe. For vertical-lift gates designed for major overflow heads, this is doubtless true in order to prevent vibration. With other types of gates or on overflow crests either without gates or with undershot gates, this may not be so apparent. For example, drum gates, such as those on the crest of Grand Coulee Dam or those on the spillway crest at Boulder Dam, may withstand the effects of considerable subatmospheric pressure without serious effect and with some resulting benefits of increased discharge.

On overflow spillways without crest gates, advantage should be taken of the fact that the efficiencies of such crests can be increased by not aerating the underface of the nappe, and it is that phase of the subject the writer wishes to discuss briefly.

At flood-control dams it has been the practice to design for great overflows under high heads. The cost of the spillway thus becomes a large part of the total developmental cost. Adding some portion of an atmospheric head to the water head, therefore, presents opportunities for more economic design. Of course, the increased load on the spillway section, resulting from subatmospheric pressures beneath the overflowing sheet, must be taken into account, but it will be found they need give little concern in the gravity type of overflow dams.

Suppose a crest profile is adopted that will be just at the limit of form to produce no subatmospheric pressures in the interface between nappe and concrete for a given design head, H_d. Then if the head is increased to some greater value H_o, the discharge coefficient will also be increased because of the creation of subatmospheric pressures at the interface, and a consequent addition of some atmospheric head to the water head.

The magnitude of these increases was investigated[11,12] by Hunter Rouse, M. Am. Soc. C. E., and Lincoln Reid, Assoc. M. Am. Soc. C. E. It was shown that the design head might be increased several times with continually increasing coefficient before separation of the nappe. These increases check fairly well with the increases in discharge given in Fig. 10, as the following example will show.

---

[11] "Model Research on Spillway Crests," by Hunter Rouse and Lincoln Reid, *Civil Engineering*, January, 1935, p. 10.

[12] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, McGraw-Hill Book Co., Inc., New York, N. Y., 1st Ed., p. 316.

The No. II profile of overflow crest of the Rouse-Reid experiments[13] was used. A design head of 6.0 ft was selected for which $C = 3.51$ and $q = 52$ cu ft per sec per lin ft of spillway crest. The percentage increase in C then becomes the percentage increase in Q due to subatmospheric pressures at the interface. Table 8 shows the calculations, which are explained by the notes. Comparing the quantities in Cols. 4 and 11, they are seen to check fairly well with the limit of the curve in Fig. 10.

TABLE 8.—INCREASE IN DISCHARGE FROM REDUCED PRESSURES BENEATH THE NAPPE

Explanation: Col. 3, from Rouse-Reid experiments; Col. 4, same as increase of C (in Col. 3) over $C_d = 3.51$; Col. 5, calculated from $q = C\,(H_e)^{3/2}$; Col. 7, $H' = \left(\frac{q}{3.51}\right)^{2/3}$ (this would be the head if there were no subatmospheric pressure at the interface); Col. 9, read from curve of Fig. 10 with $\frac{H_e}{H'}$ as the argument; Col. 10 = Col. 9 × Col. 1; and Col. 11, read from curve of Fig. 10 with $\frac{p}{H_e}$ as the argument.

12	2.00	3.91	11	162	46.1	12.9	0.931	0.57	6.8	12.0
14	2.33	4.02	14	211	60.0	15.3	0.915	0.75	10.5	14.8
16	2.67	4.12	17	264	75.1	17.8	0.904	0.96	15.4	....
18	3.00	4.19	19	320	91.2	20.3	0.887	1.05	18.9	....
20	3.33	4.26	21	381	108.5	22.8	0.878	1.08	21.6	....
22	3.67	4.30	23	444	126.5	25.2	0.873	1.10	23.2	....

It is obvious from the foregoing that the savings in cost are important enough to warrant further development of the thesis that spillway discharges can be increased materially and safely by designing for subatmospheric pressures beneath the nappe.

This would be particularly useful for flood-control dams. The design head would produce no subatmospheric pressures; and hence all ordinary floods would be passed with atmospheric pressure beneath the nappe. For the 1-in-100-yr or 1-in-1,000-yr flood, subatmospheric pressures of as much as $p = 30$ ft of water (which would increase discharges about 25%) could be provided for. This would permit either (1) reducing the spillway length to 80% of what would otherwise be required for the same head; (2) lowering the height of dam by 16% of the maximum overflow head and thereby reducing flood damages upstream; or (3) increasing the height of spillway crest for greater storage and power head if the pool level be fixed at some definite upper limit.

Little or no damage to the concrete, by pitting, could result from such intermittent use even if the pressure at the interface should fall to that of the water vapor and cavitation should result. If pitting should occur during a protracted flood, repairs could readily be made before the next flood would occur.

---

[13] "Model Research on Spillway Crests," by Hunter Rouse and Lincoln Reid, *Civil Engineering*, January, 1935, p. 11, Fig. 2.

It would seem, therefore, that those agencies concerned with the design and construction of flood-control spillways would see that the experiments described by the author were extended to include a further study of spillways without crest gates. It would be a decided advantage, in such studies, if the models could be enclosed and the atmospheric pressure within adequately controlled.

G. H. Hickox,[14] M. Am. Soc. C. E.—The discussions of this paper leave very little to be added in closing.

The writer is not quite in agreement with Professor Johnson that the increase of discharge occurring with reduction of pressure beneath the nappe is caused by expanding the cross section of the nappe. The cross section may expand, but the writer prefers to attribute the increase in discharge largely to the increased velocity, which must exist because of the larger pressure difference on the lower side of the nappe.

Mr. Johnson and Messrs. Howe and Lomax remark on the lessened air requirement when air circulates beneath the nappe. The amount of air circulating depends principally on the size of the eddy in the tailwater beneath the nappe. The size of this eddy is affected by the depth of tailwater, the height of fall, and the slope of the downstream face of the spillway. In the spillways for which the experiments were made, the nappe fell on the sloping face of the spillway and no air circulated. Provision of aeration vents for the maximum air requirement will always be safe and ordinarily will not be excessively expensive.

The agreement between the writer's experiments and the independent work of Messrs. Howe and Lomax with respect to the effect of pressure reduction on discharge, as shown in Figs. 14 and 15, is very gratifying. The use of Eq. 15 will eliminate the need for Fig. 10. The data of Messrs. Rouse and Reid, cited by Mr. Stevens,[11,12,13] also show good agreement with Fig. 10.

It was not assumed, as Mr. Stevens suggests, that it is always desirable to prevent subatmospheric pressures. In the case of the dams for which the studies were made, it was necessary to prevent the pressure beneath the nappe from being lowered to a point that would endanger the safety of the gate. In the case of the field tests described, the average hydrostatic head on the lower leaf was increased from a normal value of 29.5 ft to 39.2 ft. If the pressure beneath the nappe could have been reduced to the vapor pressure of the water, the average hydrostatic head on the gate would have amounted to more than 60 ft. This is twice the maximum load for which the gate was designed and does not consider any secondary effects that might be caused by vibration.

Mr. Stevens' suggestion that spillways be overloaded to increase their discharge capacity appears to have merit, if the overload condition is provided for peak discharges only and not designed for regular operation. In the present state of the knowledge of cavitation phenomena it is not safe to assume that cavitation damage will not occur, and until further knowledge of this subject is available it would seem wise not to invite it. Excessive damage should not occur during short periods of operation, however, and if the spillway face remains dry for long intervals, it would be possible to make any needed repairs. It would seem that the possibility of effecting economics by overloading spillways for short-period peak discharges could well be investigated in future designs.

CONCRETE RESERVOIRS OF THE VERTICAL-BEAM TYPE

By C. Maxwell Stanley, Jr.,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Lewis A. Schmidt, Jr., Victor H. Cochrane, R. E. Koon and J. C. Gearhart, Gustavo Pérez Guerra, and C. Maxwell Stanley, Jr.

Synopsis

Covered concrete storage reservoirs can be designed by a "vertical-beam" method that offers advantages over conventional types. The method, which is presented herein, utilizes side-walls constructed as simple vertical beams with supports arranged at top and bottom to resist the internal horizontal pressure. The designation "vertical beam" is taken from this wall construction.

With such a design, all of the concrete in contact with the contained water is in compression. Simple methods are afforded for minimizing temperature and shrinkage stresses. These features reduce the formation of cracks on the interior face of the structure and thus, by preventing seepage into the wall, increase the resistance of the structure to deterioration. These advantages are obtained without increase in construction cost over conventional types.

Design Problem

Reservoir Experience.—The design of concrete storage reservoirs is difficult, particularly in climates having severe winters. Many cases of unfortunate experiences with concrete storage reservoirs have resulted from a lack of appreciation of the fundamental design principles.

The designer must obtain a watertight, structurally safe reservoir at a minimum cost. The wall must act both as a membrane preventing the flow of water from the reservoir and as a structural member resisting internal pressure. To fulfil the first function, the walls must be impervious and free from cracks. As it fulfils the second, it must deform to resist stresses and, as it deforms, it will crack wherever appreciable tensile stresses occur. Even though these cracks do not result in objectionable leaks, they permit saturation of the concrete which may lead to rapid damage from freezing and thawing. Even the use of

---

[1] Cons. Engr. (Stanley Engineering Company), Muscatine, Iowa.

low steel stresses will not eliminate cracks entirely. If the designer can select the design in which the concrete surface presented to the water remains in compression and is free from uncontrolled cracks, he will have done much toward the elimination of seepage into the concrete, with its ensuing deterioration.

Criteria of Wall Design.—The following are listed as criteria of an ideal wall design that will minimize and control cracks:

(1) Concrete in contact with water must be in compression;

(2) Walls must be poured in sections sufficiently small to avoid excessive shrinkage cracks;

(3) The entire structure must be so designed that expansion and contraction may be controlled to avoid cracking of surfaces in contact with water; and

(4) Construction joints must be kept to a minimum, and every construction joint must be treated as an expansion joint.

The failure of conventional types of reservoirs to measure up to these criteria led to the development of the "vertical-beam" design.

VERTICAL-BEAM TYPE

General Description.—As the name implies, the side-wall (see Fig. 1) acts as a simple vertical beam resisting the internal water pressure, with the horizontal reactions taken by suitable supports. The bottom of the beam sets in a recess in the footing which is designed so that the wall may rock slightly with changes in temperature and loading, and thus avoid rigidity.

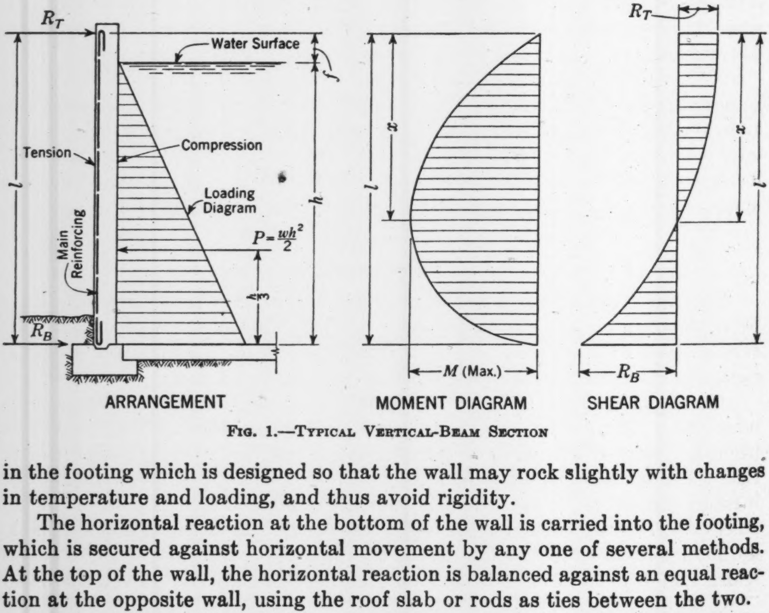

FIG. 1.—TYPICAL VERTICAL-BEAM SECTION

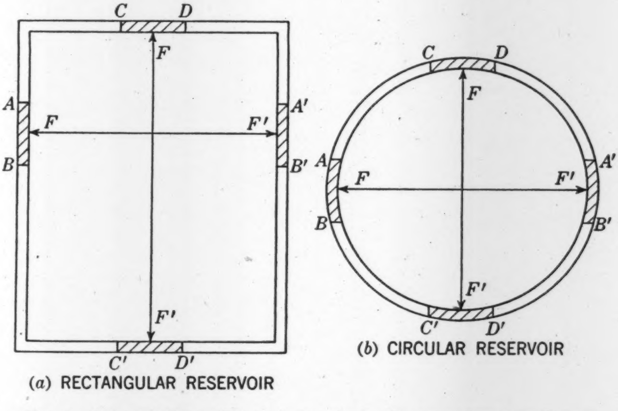
The horizontal reaction at the bottom of the wall is carried into the footing, which is secured against horizontal movement by any one of several methods. At the top of the wall, the horizontal reaction is balanced against an equal reaction at the opposite wall, using the roof slab or rods as ties between the two.

Sections of the side-wall are constructed in one pour from the footing to the top, thus eliminating all horizontal construction joints. The length of wall sections between vertical joints is kept reasonably short to limit the size of pour and to avoid extreme shrinkage or temperature stresses. All vertical construction joints are treated as expansion joints and are carefully sealed against leakage.

The main steel reinforcement is placed vertically near the outer face of the wall. Temperature steel (not shown in Fig. 1) may be placed horizontally near the outer face and vertically and horizontally near the inner face. The steel from the footing into the beam (if used) is placed in the plane of the main reinforcing near the outer face of the wall.

This design affords a construction in which cracking is minimized by placing in compression all concrete in contact with the water and by carefully providing for temperature and shrinkage stresses. The stresses in the wall may be computed readily by simple structural analysis that need not be outlined or discussed herein.

Support of Top.—Horizontal support of the top of the vertical beam relies upon the symmetry of the structure, which permits the balancing of horizontal forces on opposite sides of the reservoir as shown in Fig. 2. The forces F and F' will be equal in amount and opposite in direction whether the reservoir is circular, square, or rectangular. The two forces may be balanced by providing a suitable connecting member between the opposite walls. Three different methods are shown in Fig. 3(*a*). The top support will move, due to the expansion or contraction of the tie member and to the strains resulting from the internal load. This movement is taken care of by permitting the vertical beam to rock upon its base.



(*a*) RECTANGULAR RESERVOIR

(*b*) CIRCULAR RESERVOIR

FIG. 2.—VERTICAL-BEAM WALLS ARRANGED TO BALANCE OPPOSING FORCES

Support of Bottom.—The bottom of the vertical beam may be supported either by balancing opposing forces, as described for the top of the beam, or by utilizing a horizontal force resulting from the reaction of the wall on the earth or rock or from friction on the base.

Four different arrangements for supporting the bottom of the beam are shown in Fig. 3(*b*). In each of these designs the bottom of the wall is detailed so that it will be free to rock about its base. If tie rods are used between the footing and the wall, they are located in the plane of the main steel reinforcement near the outer wall to avoid tension at the bottom of the slab. A seal (not shown in Fig. 3(*b*)) must be provided to prevent leakage through the horizontal joints where the wall joins the footing. All of these arrangements avoid tension in the surface of the wall that is exposed to the water.

FIG. 3.—METHODS OF SUPPORTING THE WALLS

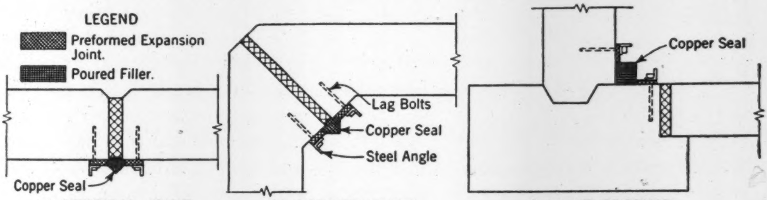
Provision of Expansion and Contraction.—Expansion and contraction are taken care of by limiting the dimensions of each pour and by designing the structure with a flexibility that will permit movement of the walls without damage to the structure.

Horizontal construction joints are eliminated and each vertical wall section is limited to such length as will avoid shrinkage or contraction cracks. In the original designs, sections of 30 ft to 40 ft were used, in keeping with customary practice in other concrete structures. However, vertical cracks have developed in sections of this length and are apparently the result of continued contraction. Therefore, more recent designs have used shorter lengths of wall (less than 20 ft) to eliminate such cracking. Temperature steel may be used as required in the faces of the wall, but should not extend through the vertical construction joints. Expansion joints are used between adjacent wall sections.

Corners of square or rectangular reservoirs are constructed with expansion joints arranged so that movement, or rocking of the wall, will not be resisted by the corners. Changes in temperature will result in the expansion and contraction of the roof slab or supporting members holding the top of the vertical beam. When this occurs, the vertical beam will rock slightly on its base, without changing the stress relationship within the member, as there is no rigidity in the connections between the wall, footing, and roof. Differences in temperature between the inside and outside of the reservoir will cause differential expansion or contraction of the inner and outer surfaces, and the wall will tend to assume a slightly curved section. However, as the wall is not restrained at either top or bottom, it may be distorted in this manner without harm.

Waterproofing.—Waterproofing is required on the wall at the vertical expansion joints and at the horizontal joints between footing and wall. The walls require a waterproofing treatment to fill the pores and increase imperviousness. Several kinds of waterproofing may be used, but very satisfactory results have been obtained with a cement grout containing iron filings.

The expansion joints are composed of poured or premolded material of suitable thickness and require some type of noncorrosive metal steel. After some unsatisfactory experiences with copper seal of conventional design, an externally mounted seal has been developed. The seal, shown in Fig. 4(*a*), is installed after the wall is poured and is thus accessible during installation and for maintenance. Its cost is probably a little more than a conventional seal, but any extra cost is fully warranted by its simplicity and dependability (see also Fig. 4(*b*) for a seal at the corner joint).



(*a*) VERTICAL JOINT (*b*) CORNER JOINT (*c*) AT FOOTING

FIG. 4.—TYPICAL SEALS

The joint between the wall and footing also must be made tight, and this can be accomplished either by a modification of Figs. 4(*a*) and 4(*b*) or by the use of a more conventional copper seal (Fig. 4(*c*)). If the head of water within the reservoir is small, the copper seal may be omitted and the joint can be sealed with bituminous material.

Backfilling.—Although the vertical-beam design is intended primarily for reservoirs located above ground, the side-walls may be partly backfilled without any modification of the design. Under such conditions, the simple beam acts as a cantilever with the main reinforcement carrying the tension and with the inner face of the wall remaining in compression. Dowels must then be used near the outside face to tie the wall to the footing; and, at the top of the wall, a type of support must be used in which the wall is free to move inward. A considerable depth of backfill may be placed without requiring any increase in wall section. The footing must be of adequate design to prevent the wall from overturning.

EXPERIENCE WITH VERTICAL-BEAM RESERVOIR

Actual construction and use are the final test of any design. A critical examination of experiences with the vertical-beam design reveals its advantages as well as the problems that have arisen. Both difficulties and advantages call attention to needed changes in details of design and construction. Data on three such reservoirs that have been constructed and used are shown in Table 1.

[a] Corresponding to project numbers in Fig. 5. [b] Spacing of expansion joints. [c] Each of two compartments. [d] Joint spacing 30 ft to 40 ft.

Typical details of wall construction and wall support for these three reservoirs are shown in Fig. 5. Experiences during the construction of the reservoirs, and observations after they had been placed in service, have disclosed defects that have been remedied in subsequent designs.

The arrangement of tie rods and struts in the first project (Fig. 5(*a*)) was very effective in preventing the movement of footings, but it was costly and was slow to construct. Even before the job was completed, the simpler arrangements for bottom support shown in Figs. 5(*b*) and 5(*c*) were developed for use in subsequent designs. These arrangements permit the tightening of tie rods after all other construction is complete.

The method of top wall support in the first project (slab rigidly connected to wall) hindered the free action of the wall. Cracks developed immediately over each vertical wall joint and extended back into the roof slab. Also, diagonal cracks developed across each of the roof slabs some 8 ft or 10 ft back from the intersection of the outside wall. This crack was matched by vertical cracks in each of the walls a like distance from the corner. All these cracks seemed to be the direct result of restricting the free action of the wall and roof by a rigid interconnection. This led to the development of other methods of top support (see Fig. 3(*a*)) that permitted free action of roof and wall, and these methods were adopted in subsequent designs.

Trouble with the expansion joints used on the first project developed when the reservoir was filled. Efforts to repair them were generally unsatisfactory until a seal similar to that of Fig. 4(*a*) was used. This type of seal has been so

FIG. 5.—TYPICAL DETAILS OF SIDE-WALLS

effective that it has been generally applied not only on successive reservoir designs, but on other hydraulic structures.

The most serious problem encountered in the first designs was the formation of vertical cracks between construction joints. On the first structure (Fig. 5(*a*)), these cracks were not apparent when the structure was placed in service, but have developed gradually over the years. On the second reservoir (with lighter walls), the cracks were observed before construction was completed (see Fig. 5(*b*)). Their location and development indicate that they are the result of contraction and shrinkage stresses and that the 30-ft to 40-ft intervals between expansion joints are too large for the differential temperature stresses which occur in an exposed reservoir wall. The last design (Fig. 5(*c*)) used a much smaller interval between joints, and no vertical cracks have been observed.

The aforementioned troubles, although annoying, have not been serious and are probably no more than may be expected with any new design. The reservoirs that have been constructed have demonstrated the soundness of the theory of design. The construction is simple, and costs are low. The walls have acted as planned and have rocked with the expansion of the roof. The corner and intermediate vertical joints have reacted as expected. The reservoirs are giving satisfactory service and the troubles encountered have only served to improve subsequent design. The same principle of vertical-beam construction has been applied to several other structures.

CONVENTIONAL DESIGNS

The more common designs that have been applied to storage reservoirs include the following:

(1) Circular walls acting as shells to resist internal bursting pressure.
  (*a*) Conventional type with tension steel in concrete.
  (*b*) A pre-stressed reinforcement type developed by William S. Hewett, with tension steel outside the concrete.

(2) Retaining walls utilizing the weight of the impounded water to resist the outward pressure.
  (*a*) Cantilever.
  (*b*) Buttress or counterfort.

A description of each of these types and a statement of their obvious advantages and disadvantages follow.

Circular Walls.—Both the conventional and pre-stressed type of circular walls are based on the same fundamental theory. The walls are designed as shells to resist the bursting pressure of the water within the reservoir. The tension at any point on the wall varies with the diameter of the reservoir and the depth of the water. As concrete cannot resist tensile stress of substantial magnitude, circular hoops of steel must be used. The area of steel required will vary directly with the depth. In the conventional design, the steel is embedded within the concrete wall, whereas in the pre-stressed design the steel is placed around the wall and is pre-stressed.

The placing of the steel within the wall in the conventional design creates a serious problem, as the forces acting on the wall tend to increase its circumference, and the concrete, having limited elasticity, is cracked. Nothing can be done to prevent this cracking although the size of cracks may be controlled. Attempts often are made to avoid cracking by limiting the stress in the steel to about 9,000 or 10,000 lb per sq in., but even under these conditions some cracking is likely to occur. Furthermore, other cracks result from horizontal and vertical construction joints and from temperature and shrinkage stresses.

The disadvantages of the conventional circular reservoir are superbly overcome in the pre-stressed type, which has been quite widely used in recent years since this design separates the membrane from the structural member. This is accomplished by placing the hoop steel outside an inner membrane composed of narrow, vertical, concrete slabs without horizontal joints. The slabs are pulled together by tightening turnbuckles in the circular hoops, thus pre-stressing both slabs and hoops to such a point that, even with the reservoir filled, the slabs are still in compression. This design, with its pre-stressing, readily cares for shrinkage and temperature stresses and achieves the goal of all reservoir design—an inner concrete membrane placed in compression and free from cracking. Its only disadvantages are its mandatory circular shape, and the relatively high cost for certain ratios of depth and diameter.

Retaining Wall Types.—Wall designs of the retaining wall type depend primarily on the weight of the water within the reservoir to offset the overturning moments exerted by the water pressure on the side-wall. Either the cantilever or buttress type may be used. With the cantilever type, the entire inner face of the vertical wall is placed in tension, together with the top surface of the footing within the reservoir. With either buttresses or counterforts, the vertical wall and the base slab are designed as horizontal beams and are usually constructed continuously past two or more supports, thus placing a part of the inner face of the vertical wall and the top face of the footing in tension.

Thus, when the principles of a retaining wall are used with either type of design, a part, or all, of the concrete in contact with the water will be in tension. Such design also requires a rigid structure that does not lend itself readily to the elimination of horizontal construction joints, or to the minimizing of cracking due to temperature or shrinkage stresses.

Appraisal of Vertical-Beam Design

The vertical-beam method of reservoir construction has been developed and tested so that its advantages and disadvantages can be established reasonably well. Reservoirs may be designed successfully, using the vertical-beam method, provided that the details which have given trouble are avoided. The following conclusions may be drawn:

(1) The basic theory of the "vertical-beam" reservoir is sound. The tendency for concrete to crack is minimized by placing all wet surfaces in compression and by providing sufficient flexibility in the structure to reduce the tendency toward cracking from temperature movements and stresses. None of the conventional designs (except the pre-stressed concrete type) accomplish this.

(2) The vertical-beam type of reservoir offers extreme simplicity of both design and construction. Structural analysis is direct and not complicated. Construction is concerned only with plain sections and surfaces.

(3) The construction costs of vertical-beam reservoirs compare favorably with the conventional types. The flexibility of the vertical-beam type of construction and the absence of rigid connections permit the efficient use of concrete and steel and allow the selection of relatively thin sections. These facts, together with the simplicity of construction, permit economy.

(4) The design is most aptly suited to rectangular, or square, reservoirs. Although it may be applied to circular reservoirs, the latter must be of large diameter and the vertical sections must be made sufficiently short so that horizontal bending stresses will not be developed in the curved sections.

(5) The design has been limited to depths such that the vertical walls can be poured in one lift. It may be possible to use horizontal construction joints with suitable seals, but it seems that a better design will be obtained if this is avoided.

(6) This type of construction is limited as to the amount of backfill that may be used on the outside. Under backfill conditions, the vertical wall acts as a cantilever, and its strength as such is limited.

(7) This type of design is also probably limited to those cases where good foundations are available. If a reservoir must be constructed upon soft foundations, a continuous base slab probably will be dictated.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the suggestions that have been made by Arthur E. Stanley, Assoc. M. Am. Soc. C. E., and by Herman S. Smith and Allen H. Dunton, Juniors, Am. Soc. C. E., who have been associated with him in the preparation of the detailed designs of these reservoirs.

DISCUSSION

Lewis A. Schmidt, Jr.,[2] M. Am. Soc. C. E.—An interesting argument for vertical-beam type reservoirs is contained in this paper. Without doubt there are many applications for this construction.

Regarding vertical cracks developing in project 1 and project 2, Fig. 5, and not in project 3, it is quite likely that the added percentage of horizontal reinforcement (from 0.17% and 0.14% to 0.34%, respectively) contributed as much to the reduction of these cracks as did the shortening of the length of the pour. There is a decided construction economy in the reduced number of pours, because of the decreased number of joint seals that must be placed. Where comparatively thin walls are exposed to atmosphere on one or both sides, a proportion of $p = 0.5\%$ in each direction for temperature reinforcement is not unusual. This amount of steel would probably be justified by the aforementioned economies, and would perform the same function.

The concrete placement in the very thin walls of projects 2 and 3 is also diametrically opposed to achieving least shrinkage, since so thin a wall, 10 ft high, and with steel on one or both faces, almost dictates the use of high slump concrete. Concrete which can be placed with lower slumps gives added assurance of less shrinkage cracks, so some thought might well be given to a minimum wall thickness of about 12 in., which could be built with a drier concrete without danger of honeycombing and with less water to be dehydrated. It seems probable that the disparity of roof thicknesses between projects 1 and 2 contributed to the cracking in project 1 as much as the restraint offered by the rigid connection.

The author mentions that conventional copper seals have not proved to be satisfactory. These have been used so often in heavy construction, particularly in conjunction with premolded joints, that it would be desirable to set forth their deficiencies in the reservoirs.

Mr. Stanley advisedly calls attention to limitations of the design, and undoubtedly the seventh one would be very important in this case, especially where the bottom slab rests on the footing as well as on the foundation. Differential pressures at this point due to the wall load could contribute some unequal settlement and cracking, particularly of the bottom slab.

This type of construction may be expected to show up to best advantage in square or rectangular rather than circular structures. Within its limitations it would be interesting to see a comparative cost analysis of various designs.

Victor H. Cochrane,[3] M. Am. Soc. C. E.—The clear presentation of the advantages and limitations of the vertical-beam type of reservoir and the discussion (based on the author's experience) of both desirable and faulty details of construction make this paper a valuable contribution.

A reservoir of this type, built in the spring of 1942 for a large army cantonment in the Southwest, was designed under the direction of the writer. The capacity of 3,000,000 gal is sufficiently large to permit the elimination of conventional steel elevated-tank or standpipe storage. As the reservoir is located on a hill of suitable elevation, the shape of the limited area on top dictated the use of a circular reservoir. Earth was used for backing and for a roof cover 18 in. in thickness in order to improve the quality of the stored water, to minimize temperature variations, and to effect concealment of the structure. The inside diameter is 164 ft and the depth of water, 20 ft. The rock face of the foundation trench is relied upon to resist that part of the bottom reaction of the wall sections not taken care of by the earth backing. The support of the top of the wall is similar to that shown in the middle detail of Fig. 3(*a*). There are twelve vertical joints at intervals of 43 ft. The weight of reinforcement required was found to be only about one half as great as for a conventional hoop-tension reservoir.

---

[2] Acting Constr. Engr., TVA, Hales Bar Dam, Chattanooga, Tenn.

[3] Cons. Engr., Tulsa, Okla.

This structure departs from the author's recommendations in the following particulars: (1) It is circular in plan, for the reason previously stated; (2) it is covered and backed with earth; and (3) the length of the wall sections is greater than recommended. In general, these departures may be explained by the fact that the reservoir was expected to be in use not more than five years, thus making the requirements less severe than for a permanent structure.

From the structural point of view the earth covering is advantageous in some respects as it greatly reduces the temperature range and, at the same time, protects the concrete from the effects of freezing and thawing. Since the inward earth pressure is about one half as great as the outward water pressure with full reservoir, the inner face of the wall will remain in compression except when the tank is empty or drawn down to an unusual extent. If some small cracks should appear under these conditions, they should close when the reservoir is filled above the normal drawdown level.

Experience has shown that, unless extraordinary measures are employed, a concrete wall resting on earth or rock and exposed to extreme ranges of temperature tends to crack at intervals of 15 ft to 20 ft, and therefore the statement that the wall sections should be less than 20 ft long between joints is correct. As the author suggests, horizontal bending stresses may be set up in long sections because the vertical-beam elements are somewhat restrained from bending radially. The section is strengthened by this action unless cracking occurs. In the present instance it was felt that the earth protection and the short period of use justified the joint spacing adopted.

The structure has been in use since June, 1942, and no defects of consequence have been reported. The circular structure is free from the undesirable conditions occurring at the corners of rectangular reservoirs. It will be interesting to note whether any objectionable cracking occurs.

In his discussion of retaining wall types (see heading, "Conventional Designs: Retaining Wall Types"), the author omits reference to the arch-wall design, such as that developed by the writer for a 1-million-gal clear well of the water treatment plant near Fort Smith, Ark. Several descriptions of this reservoir have been published.[4] This type of structure seems to eliminate all the objectionable features listed by the author, and, in addition, it has some advantages.

---

[4] *Engineering News-Record*, September 17, 1936, p. 400; also *Water Works Engineering*, August 19, 1936, p. 1068.

The Fort Smith reservoir is circular, with a 20-ft depth of water, and the wall consists of twelve arches of 25-ft span, 8 in. in thickness, springing from radial buttresses with counterfort extensions. Foundations are in hardpan, and the structure is earth covered. The arches preferably are poured in stages, the forms being raised as the concreting progresses. The entire wall, including the joints between arches and buttresses, is in compression. Experience with multiple-arch dams indicates that such joints are not likely to leak, and, since there is no tendency for the joint to open, simple and inexpensive stopwater elements may be used. The only joint requiring special treatment is that between arches and footings. Temperature effects are taken care of by the flexibility of the arches. The roof is of beam and slab construction, with exterior columns located at the heel of the counterforts to lend stability to the wall.

A design was also made for a pre-stressed tank with a domed roof. The quantities required for the two designs were found to compare as follows:

	Arch-wall design	Pre-stressed wall design
Reinforcement, lb............	94,000	112,000 (including turnbuckles)
Concrete, cu yd..............	672	650

For an aboveground reservoir of the arch-wall type the quantities required would be considerably less than the foregoing. The Fort Smith tank has been in service since 1936, and no leakage has been observed and no defects have developed.

TABLE 2.—ECONOMIC DEPTHS FOR SQUARE ARCH-WALL RESERVOIRS

Reservoir	Cost C_1 (dollars per sq ft)	Constant k	CAPACITY, IN MILLION GALLONS:							
			0.1		1.0		3.0		10.0	
			Depth h	Length[a] l	Depth h	Length[a] l	Depth h	Length[a] l	Depth h	Length[a] l
Volume V (cu ft)...	....	....	13,400		133,700		401,000		1,337,000	
Covered...........	1.50	1/10	9.9	37	15.7	93	19.5	144	24.8	232
Open..............	0.50	1/12	....	....	10.9	111	13.6	172	17.2	279

[a] Length of side; all dimensions are in feet.

This kind of reservoir is unlimited as to size and virtually unrestricted as to shape. The roof may be of any construction, or it may be omitted entirely. The greater the capacity, the less will be the cost per unit of storage. If a cover is provided, a square or rectangular shape is preferable.

The economic depth for square arch-wall reservoirs is given by the formula

$$h = \left(\frac{C_1}{k}\right)^{2/5} \frac{V^{1/5}}{2} \qquad (1)$$

in which h = depth of water in feet; C_1 = cost of floor, roof, and roof covering, in dollars per square foot of reservoir area; V = volume of storage in cubic feet; and k is a constant.

The cost of the wall varies approximately as the square of the height, and $k = \frac{C_2}{h^2}$ (assumed), C_2 being the cost of the arches, buttresses, and backfill (if any) per linear foot of wall. Table 2 shows typical variations in economic depth for covered and uncovered reservoirs for assumed values of C_1 and k. The depth may be varied either way from the most economic value without greatly increasing the cost.

R. E. KOON,[5] M. AM. SOC. C. E., AND J. C. GEARHART,[6] ASSOC. M. AM. SOC. C. E.—Having, presumably, investigated the merits and deficiencies of covered concrete reservoirs built according to "conventional design," the author concludes that such structures can be built, to advantage, with "vertical-beam" side-walls. This conclusion was reached as the result of theoretical analyses and actual construction experience. Only the vertical-beam type is detailed in the paper, but it may be inferred from the text that the "conventional" type had been tried with unfavorable results. The author classes as "conventional" cantilever walls or buttress-supported walls and also hoop-reinforced walls of round reservoirs except those wherein the steel is pre-stressed. This definition seems adequate and is accepted for purposes of reference herein.

This discussion deals with certain of the author's conclusions which the writers cannot accept as well founded in theory, or established as the result of their own practical experience.

General Comments.—The data presented in support of the author's conclusions are limited, in all practical aspects, to observations on one reservoir of moderate size (3 million gal) in which several defects appeared, and to two quite small reservoirs (0.12 million gal and 0.10 million gal, respectively) in which changes in details of design were made to correct for defects observed in the earlier structure.

In general, the writers have favored the author's so-called "conventional design." An exception has been made in the case of relatively small structures, mainly settling basins ahead of mechanical filters, where the lengths of tie beams have been rather short. As a consequence of these experiences, this paper favoring vertical-beam construction for reservoir walls has been read with much interest.

Adverse Conclusions.—The writers' conclusions are quite contrary to those reached by Mr. Stanley. The importance of his assumptions of deterioration of concrete-embedded steel also is questioned. Supporting and explanatory discussion will follow, but an outline of these adverse conclusions is summarized thus:

---

[5] Cons. Engr. and San. Engr. (Stevens & Koon), Portland, Ore.

[6] Ensign, CEC-V(S), U.S.N.R., Camp Peary, Williamsburg, Va.; formerly Asst. Engr., Stevens & Koon, Portland, Ore.

1. Except under certain unusual conditions, there will be no advantage in the "vertical-beam" walls either structurally or economically;
2. To assume that defects which appeared in a 3-million-gal reservoir have proved to be corrected fully by changes made in design of later structures, each of which is less than one twenty-fifth the size of the original structure, is not convincing;
3. Structures of "conventional" design are not more subject to leakage than are those of the vertical-beam type;
4. It is not necessary to apply surface waterproofing to walls of "conventional" type which have been built properly (this is also true of walls of the vertical-beam type);
5. No evidence has been produced by the author, nor have the writers found it in literature, to the effect that water entering the minute cracks (which theoretically appear in properly stressed concrete walls) will cause injury to reinforcing steel;
6. The use of vertical-beam walls in place of cantilever walls does not effect a simplification of design; nor does it afford appreciable advantage to the builder;
7. Steel tie rods required by vertical-beam construction, unless specially protected, are more vulnerable to deteriorating action than concrete-encased reinforcement as used in walls of "conventional" design;
8. The writers find that an analysis of relative costs favors "conventional" design in the ratio of about 5 : 4;
9. Application of the vertical-beam theory to round reservoirs would develop extraordinary problems in tie-rod arrangement which should preclude any attempt to use such a design; and
10. Although the design of a reservoir with vertical-beam walls may be theoretically sound, the possibilities of major structural failures due to defective workmanship, particularly with respect to tie-rod placing and adjustment, seem very great as compared with an equally well-designed structure with walls of the "conventional" type.

Basic Theory.—The author's theory, that the use of an adequately supported vertical beam to carry the load due to water pressure in a reservoir is feasible, cannot be disputed; but the application of this theory cannot be made properly to reservoirs of all ordinary sizes and shapes. In some instances, a reservoir must be built (*a*) of small capacity, (*b*) with necessarily high vertical walls, (*c*) square or rectangular in plan, and (*d*) where the steel tie members can be encased in good concrete. In these cases, the writers agree with the author as to the soundness of application of the theory but only if its use will show economy in construction cost as compared to a design of "conventional" type. In short, a good reservoir can be built using either type of wall design. Architectural requirements or foundation conditions may be determining factors in the selection of the type of wall to build. In another case the designer's preference, influenced by his personal appraisal of the relative merits of compression or tension in the wetted wall face, may determine the final choice.

Few reservoirs, however, must conform in all respects to the foregoing stipulations. Usually the designer has several options: The reservoir may be relatively shallow and consequently may cover a greater area; it may be made round in plan and relatively shallow or deep; and it may be built with a considerable part, or all, of the water capacity below or above natural ground level. All, or some, of these alternates may be, and usually are, available for the designer's choice, and his determination to give predominant weight to any special condition perhaps will be influenced by many factors. In some instances, certain unalterable facts—the elevation of the available site in relation to a fixed requirement for elevation of the water, the nature of the foundation or of the material to be excavated, architectural requirements, and perhaps others—may be conclusive in dictating the type of reservoir wall to be built; but such circumstances are rare. For purposes of this discussion, it is understood that certain basic requirements only remain unchanged: (*a*) The reservoir must be built of reinforced concrete; (*b*) it is to be provided with a roof—presumably of concrete, but not necessarily so; (*c*) it must have the required capacity; and (*d*) it must be a well-built structure, free from leakage.

Only rarely will there be such a combination of all circumstances as clearly will favor the designer's selection of the vertical-beam type of wall; and, consequently, the application of this "basic theory" of vertical-beam construction to all concrete-covered reservoirs or, indeed, to more than a negligible few, is not sound.

Effect of Cracks in Concrete.—It is regrettable that so little information has been published on the appearance of cracks, either visible or microscopic, in reinforced concrete members under normal loads. The stresses within a vertical wall subjected to hydraulic loading can be calculated very precisely, and, consequently, the deformation of such a wall can be determined with reasonable accuracy. Since the tensile strength of concrete alone is assumed as zero in most reinforced concrete design, it follows that minute cracks must occur in any member that suffers deformation; and deformation will occur, of course, as soon as any load is applied.

The author's principal argument in favor of the vertical-beam type of wall for reservoirs seems to be that the entire concrete surface in contact with the water is thus in compression and therefore free of cracks which might permit moisture to attack the reinforcing steel. Although the writers agree that minute cracks will develop in the inside face of a cantilever wall, they are not convinced that these cracks are of sufficient magnitude to permit water to enter and thus, perhaps, to be detrimental to the steel, unless such a wall is loaded appreciably above that allowable in normal design.

If it is assumed, because there is no evidence to the contrary, that the cracks in a cantilever wall will be large enough to permit water to contact the steel, it is evident that similar cracks of equivalent magnitude must appear on the outer or tension side of the wall designed as a vertical beam. Such cracks, although not exposed to water from within the reservoir, would be vulnerable to the attacks of rain, air, and frost if the wall is exposed to the atmosphere and perhaps even to worse conditions if the wall supports a backfill. These agents may be much more severe in their effect on the reinforcement and concrete than the reservoir water alone.

By the use of sufficient reinforcing steel, all cracks can be eliminated or so reduced in size as to remove any chance of their being deep enough to reach the steel. There is no evidence, however, to indicate that such extravagance in steel could be justified, in any way, whether the wall be of the "conventional" or the vertical-beam type.

Choice of Design.—The use of walls of the vertical-beam type in large reservoir construction may be new, but this does not signify that they have not been considered for such service. The experienced reservoir designer customarily has in mind several alternate types of structures or methods of construction for each such project; and, since there are frequent occasions to use vertical beams to good advantage in ordinary structures, it is not reasonable to assume that their possibilities for reservoirs would be overlooked. It appears, therefore, that the chief reason why this type of design is not usual, and consequently "conventional," is because safer or more economical types have been chosen.

Relative Cost of Construction.—It is stated in the paper that reservoirs with vertical-beam type of walls have been constructed without increase in cost over other types. A few calculations made by the writers do not appear to bear out this statement. Alternate designs for the author's project No. 1 and project No. 3 are submitted herewith in Fig. 6.

Since the author does not indicate the roof or floor slab reinforcement, nor the column supports for his roof in project No. 1, it is assumed that the quantities of steel would be substantially the same with either type of wall and, therefore, these quantities have been neglected in the comparisons made. In making the comparative estimates, it also has been necessary to assume dimensions which appear to be reasonable for structural details not given by the author. Likewise, it will be necessary to make similar assumptions for details which the writers could not show in their sketches.

The roof slab in Fig. 6 is shown, with a thickness of 6 in., to be comparable to the author's design for estimating purposes. This type of wall design requires slightly greater roof area. The vertical steel bars in the outside face, carried to varying elevations, are adequate for earth backfill as high as the water level, and should be omitted if there is no backfill or if they are not required as spacer bars to support temperature steel. The principal reinforcement bars in the wall and in the footing vary in lengths, as the stresses require.

The writers' alternate for project No. 1 (Fig. 6(*a*)) has a capacity of 1.5 million gal in each of two square sections, with a common wall between. This division wall is similar to the side-wall detail except that the floor has a 1-on-2 slope for a distance of 10 ft on each side.

The concrete quantity in project No. 1 (Fig. 5(*a*)), including walls, footings, and floor and roof slabs, approximates 1,895 cu yd. The reinforcing steel, neglecting that in the roof and floor slabs and assuming that no extra steel is added in the roof slab to restrain the top of the wall, is calculated to be 183,000 lb. If the concrete is estimated to cost \$40 per cubic yard and the steel \$0.06 per pound, then the total cost of these parts of the reservoir is approximately \$87,000.

(*b*) CIRCULAR RESERVOIR ALTERNATE FOR AUTHOR'S PROJECT NO. 3

(*a*) ALTERNATE FOR AUTHOR'S PROJECT NO. 1

FIG. 6

For the alternate design indicated in Fig. 6(*a*), a reservoir of equivalent capacity, with the same items of steel neglected, the concrete is estimated at 1,480 cu yd and the reinforcing steel at 131,000 lb. Using the same unit prices, the cost of these similar parts of the alternate reservoir is approximately $67,000, thus showing a saving of $20,000 in these items.

This comparison does not present quite a true picture, however. If the two reservoirs were located on identical sites, the alternate reservoir must be 5 ft lower than the all-vertical-wall type to obtain the same foundation medium. Approximately 4,000 cu yd of additional excavation would be required for the proposed alternate, but it still would show a saving of probably $16,000, or more than 18% in construction cost. Since local conditions affecting the available site elevation are as likely to favor one design as the other, this feature as related to probable cost cannot be considered here without undue extension of this discussion. However, by placing a series of foundation walls under the slope slab and wall footing and by increasing the thickness of the sloping slab to carry the load between these walls, the alternate reservoir could occupy any site suitable for the vertical-beam type; but there then would be little difference in cost of the two types. It should be noted here that the 131,000 lb of steel used in the alternate design include about 35,000 lb in the outer face of the cantilever wall to permit backfill to the full wall height. If such backfilling is not required, then an additional saving of $2,100 would be effected in favor of the "conventional" design.

In project No. 3 (Fig. 5(*c*)), the author again gives adequate details only of the wall, footing, and wall cap. Therefore, the quantities involved in these units are the only ones included in the following comparison. From the details given, the capacity of this reservoir is only a little more than 82,000 gal. There are 51.7 cu yd of concrete in the walls, footings, and cap, and the weight of the reinforcing steel (neglecting tie rods for which no data are given) is 9,200 lb. Using the same unit prices as before for comparative estimates, the cost of these parts of the reservoir would be $2,620.

For a circular reservoir of the same depth and capacity as shown for project No. 3 (Fig. 6(*b*)), the concrete, excluding roof and floor slabs, is 39.6 cu yd and the total weight of the reinforcement, with $f = 12{,}000$ lb, is 3,250 lb. The cost of wall and footing alone then would be $1,779 or 32% less than for these same features of project No. 3. The unit cost of concrete might be higher for the circular wall, but, even if this proved to be true, the round type has such distinct advantages for so small a structure that the writers certainly would select this type unless some very unusual local conditions should dictate another choice. In addition to the quantities compared, there is also the problem of tie rods and expansion joints in the vertical-beam-wall type, and their cost undoubtedly would be such as to permit the designer to double the quantity of reinforcement in the circular tank and stress the steel as low as 6,000 lb without showing an unfavorable cost comparison for the round type.

Vertical Construction Joints.—The author states that some difficulty with leaks through vertical shrinkage or contraction cracks between the construction joints occurred on his projects Nos. 1 and 2, and that, as a result, the subsequent design satisfactorily employed construction joints at 20-ft centers or less. However, since the final project listed had walls only 34 ft long, there is no practical reason to conclude that construction joints at 20-ft intervals are necessary or desirable. The writers are certain, as a result of their own experience, that such short wall sections would accomplish nothing in guarding against reservoir leakage, would increase costs, and perhaps actually would result in inferior work.

Many structural design authorities use round figures of 0.20% or 0.25% for temperature reinforcing in ordinary slab design. However, extensive tests and experiments by C. P. Vetter[7] and Walter Dreyer,[8] Members, Am. Soc. C. E., indicate that 0.60% to 0.75% of temperature steel is necessary to eliminate all possibility of cracks large enough to permit leakage from a concrete reservoir. Under conditions where maximum air temperature ranges are as much as 100° F, the writers have used materially smaller percentages of steel than here recommended, with entire success.

In project No. 1, the author used longitudinal temperature steel to the extent of only 0.17% of the cross-sectional area of the wall and, in project No. 2, it was approximately 0.14%. These low percentages of temperature reinforcing steel point quite definitely to a reason for the troubles experienced.

In the design of a 15-million-gal reservoir (built in 1939) with a 20-ft water depth and wall section somewhat similar to that shown in Fig. 6, the writers used approximately 0.35% temperature steel in main wall sections, 58 ft 8 in. long between construction joints. After this reservoir had been in use for approximately three years, there were neither visible cracks nor leakage in any of these relatively long wall sections, and a face, 475 ft long, was exposed for its entire height. Experience on this and other reservoirs of somewhat similar design has led the writers to believe that the distance between construction joints can be almost any convenient length, within reason, as long as the amount of temperature steel is adjusted accordingly. A design feature of this reservoir, which may have contributed materially to the elimination of shrinkage cracks, was the separation of all major wall sections by short closing sections which were poured not less than 20 days after the adjacent wall sections were built.

The troubles experienced by the author with shrinkage or contraction cracks in his project No. 1 are definite evidence of the undesirability of making a rigid connection between wall and roof in a structure so large. From the incomplete details given, the reader must assume that the roof slab is one continuous piece, approximately 125 ft by 185 ft on its sides. A 100° range in temperature will produce material changes in slab dimensions and, consequently, transmit very severe stresses to the wall sections. In all cases the walls will be affected much less by changes in air temperatures than the roof slab and thus will not expand or contract in harmony with it. The best solution is to support the roof slab entirely free of the walls so that movements in one will not transmit stress into the other; at least this is true in structures of such size that vertical expansion joints are required in the walls.

Tie-Rod Use Questionable.—The use of unprotected tie rods seems ill-advised when they perform so important a function in the stability of the structure. Corrosion surely will be severe when bars are placed in earth or gravel under a reservoir floor or when they are suspended below the roof slab in what is always an extremely humid atmosphere. Such steel cannot be expected to approach the life of concrete-encased reinforcement. If so used, the safety factor should be increased materially, and this, in turn, increases the steel quantity. In some way, these tie rods may be encased or protected, but construction costs will increase with any such design provisions. The difficulties of properly placing and adjusting these tie rods, together with the uncertainties and hazards attendant on their use, seems so great as to preclude use of a design which requires them even if a substantial construction cost saving could be realized.

[8] *Ibid.*, p. 1058.

Surface Waterproofing.—The author states that the walls require a waterproofing treatment to fill the pores in the concrete, thus making it impervious to water. Test results have convinced the writers that this is not necessary and adds considerably to the over-all cost of the reservoir.

The 15-million-gal reservoir previously mentioned is approximately 235 ft by 475 ft in plan, with a dividing wall to provide two square units. Although there is a 20-ft water depth when full, the floor slab is only 6 in. thick and the slope and wall sections are quite similar to those shown in Fig. 6(*a*). All joints between adjacent floor-slab panels, as well as wall sections, have flexible metal water stops embedded in the concrete. Definite artificial cracks, about ½ in. wide, were provided at the water stops in the floor, and these were filled with hot mastic after completion of the roof. (It is important that the roof be completed before the mastic joint-filler is poured as, otherwise, during and for some time after the joints are completed, the floor slabs are subject to expansion and contraction greatly out of proportion to that which occurs after the roof is in place. Unless this procedure is followed an inferior job of joint construction is quite certain to occur.) No waterproofing of any kind was applied to the concrete mix or its finished surfaces. The reservoir is underdrained completely to an open pit. At no time since the reservoir has been in service has there been any flow whatever from these drains. The soil under the reservoir is practically impervious, and, consequently, any leakage would be evidenced by flow in the drains.

Upon its completion, the reservoir was filled to capacity and subjected to a prescribed leakage test. As measured by hook gage, the water level dropped ⅛ in. in 48 hr, thus indicating a loss of approximately 4,250 gal per day, a truly negligible part of the capacity. This test was repeated after the reservoir had been in service three years, and there was no measurable change in the rate of loss. Since there have been three cycles of seasonal changes in temperature, it seems reasonable to assume that this minute loss is established permanently and is certainly undetectable through visual observation of exposed walls or open underdrains. This case is cited thus because it proves on a rather large scale that even relatively great areas of thin concrete slabs are watertight if suitable concrete is used and, particularly, if adequate care is taken to insure its proper deposition and cure.

GUSTAVO PÉREZ GUERRA,[9] JUN. AM. SOC. C. E.—The information and ideas contained in this paper should prove of great value to all members of the profession engaged in the design and construction of concrete reservoirs. In addition to considerations of watertightness (which are vital in such an undertaking), the economy in the use of concrete and the more logical design which takes full advantage of all parts of the structure point to a general adoption of this type of reservoir in the water works field.

FIG. 7.—TYPICAL DESIGN

As far as the writer knows, the first tank of the type described in this paper built in Venezuela was designed by the Water Works Division of the Ministry of Public Works (M.O.P.), early in 1939. Since then the original design has been modified only slightly. About ten such reservoirs have been built by the M.O.P., in sizes ranging from 56 to 1,200 cu m (14,800 to 317,500 gal) and with water heads varying from 2 to 4.12 m (6.56 to 13.52 ft). A typical design for a head of 4.12 m is shown in Fig. 7, in which both the floor and the roof slabs are tension members supporting the bottom and the top of the wall. The wall acts as a simply supported vertical beam for both the water and the earth loads. The bottom slab, designed as a tension member, avoids the use of tie rods, which are not desirable in Venezuela because of difficulties in inspection and maintenance.

On the other hand, it is true that no expansion joints are provided; but, since the reservoirs are intended primarily for distribution purposes and in most cases have a relatively large fire reserve, the temperature change seems to be of minor importance. Furthermore, the use of the wall as a simple beam to resist the thrust of the earth cover creates tension in the inner face of the tank walls thus discounting one of the advantages of Mr. Stanley's design. This is possible because there are no winter problems, and the cracks formed do not jeopardize the efficiency of the structure. Because of the absence of snow, the roofs of tanks in Venezuela are almost flat (slope, 1%) and are built with a parapet for the purpose of holding an earth backfill 35 cm (1 ft 2 in.) thick. Most of the tanks are partly underground and are covered by backfill, later planted with grass to improve the general appearance of the structure. However, some have been built aboveground, with no backfill. Table 3 gives data on several of the structures built in Venezuela.

Horizontal construction joints are eliminated and the walls poured in lengths of 4 to 6 m (13.1 to 19.7 ft), and in all joints 8-in. copper strips are used as water stops. The construction industry has not resorted to the elaborate and resourceful treatment, described by the author, for watertightness and expansion because local experience with this type of design has shown none of the difficulties reported in the paper. Fortunately, the absence of low temperatures reduces the importance of minute cracks in the inner face of walls. In addition, the narrow range of temperature variation during the year reduces the danger of cracking, as contraction is far more troublesome than expansion. Some temperature reinforcement is provided according to general design practice.

TABLE 3.—DATA ON VERTICAL-BEAM RESERVOIRS IN VENEZUELA

No.	Year built	CAPACITY		WATER DEPTH		AREA	
		Cubic meters	Gallons	Meters	Feet	Square meters	Square feet
1	1940	1,254	3,320,000	4.12	13.52	304.5	3,278
2	1939	553	1,460,000	4.12	13.52	134.2	1,442
3	1939	743	1,960,000	4.12	13.52	180.2	1,940
4	1941	1,239	3,275,000	4.12	13.52	300.0	3,229
5	1939	56	148,000	2.00	6.56	28.0	301

Summarizing, customary design of this type of structure in Venezuela does not comply with all the ideal wall criteria listed by the author. However, its efficiency is proved by the several units constructed, and it gives satisfactory service with only routine maintenance. The design of such tanks, irrespective of geographic or climatic conditions, will be improved greatly as a direct result of this paper which contains such valuable suggestions for designers. The favorable local experience with the original design, quite different from that described by Mr. Stanley, corroborates the known fact that tropical conditions, although producers of hardships in practically every other aspect of life, really simplify the task of the hydraulic engineer.

C. MAXWELL STANLEY, JR.,[10] M. AM. SOC. C. E.—Some of the discussers favor the vertical-beam type of construction for concrete reservoirs and some question the value of this design. Both comments are needed for a proper evaluation of any new method of design.

The examples of vertical-beam type construction given by Messrs. Cochrane and Pérez Guerra apply to conditions somewhat different from those encountered in the reservoirs described by the writer. The reservoir designed by Mr. Cochrane is of particular interest: It illustrates the application of the method to a circular reservoir of large diameter as suggested in the paper; and it extends the method to a greater degree of backfilling than the writer has considered desirable. As Mr. Cochrane states, the internal pressure normally will exceed the external pressure and cracks that may occur in the inner face of the wall when the tank is empty will tend to close when the reservoir is filled above the normal drawdown level. The arch-wall design described by Mr. Cochrane is a proper addition to the retaining wall type listed under the heading of "Conventional Design: Retaining Wall Types."

Messrs. Schmidt and Koon and Gearhart comment on the desirable percentage of horizontal reinforcement. The writer agrees that the amount of horizontal reinforcement in projects No. 1 and No. 2 is less than that desirable. Two reservoirs designed and constructed since the preparation of the paper (December, 1942) have had approximately 0.4% horizontal reinforcement which is comparable to that of project No. 3. No indication of cracking appeared on either of these reservoirs as late as fourteen months after construction.

The discussion of Messrs. Koon and Gearhart is an able presentation of the objections that may be raised against the vertical-beam design. Comments on these objections are in order. There are many factors that affect the selection of the type of reservoir, and, where those factors are such that the vertical-beam type of wall cannot be applied, obviously some other design must be used. Although the vertical-beam design is not universally applicable, it has certain advantageous features that may be utilized where it is applicable. The vertical-beam design need not be eliminated from consideration because a part of the water capacity is below natural grade, for in such cases a design similar to that shown in Fig. 8 may be used with the bottom of the wall supported by the frictional resistance resulting from the weight of the water on the base. This construction is only a modification of the method of bottom wall support shown in the lower example of Fig. 3(*b*). The vertical-beam design is not applicable to circular reservoirs, except those of relatively large diameter, but seldom is a circular reservoir required by local conditions. Rather the circular reservoir is more often the result of the type of design selected. There are few instances in which a square or rectangular shape cannot be used if desired.

---

[10] Cons. Engr. (Stanley Engineering Company), Muscatine, Iowa.

In general, the vertical-beam design may be applied where any of the "conventional designs" are considered, provided the height of wall is not too great for the wall to be poured in one lift. Moreover, local conditions as well as the ratio of depth and area will vary cost relationships between the various designs.

The hypothesis, presented by the writer, that a better design is obtained when the surfaces in contact with the water are in compression can probably be proved or disproved only by research which has not yet been undertaken. The writer believes thoroughly that having compression concrete in contact with the water is advantageous. This belief is based on his observation of numerous concrete structures and is confirmed by observed experiences with the Hewitt type of pre-stressed circular reservoir.

Vertical Force of Water on Base
R
Horizontal Force of Water on Base

FIG. 8.—APPLICATION OF VERTICAL-BEAM DESIGN TO RESERVOIR WITH PART OF STORAGE BELOW NATURAL GRADE

Cost comparisons are extremely difficult. Those made by Messrs. Koon and Gearhart assume the same unit price for concrete for the two types of construction—namely, project No. 1, Fig. 5(*a*) and the alternate Fig. 6(*a*); and, likewise, for project No. 3, Fig. 5(*c*) and the alternate Fig. 6(*b*). The unit prices for the two types of construction should not be the same. Moreover, the comparison made by Messrs. Koon and Gearhart in Fig. 6(*a*) assumes a design with only a 15-ft wall height for the cantilever type. If such an arrangement is acceptable for the cantilever type, it may also be used for the vertical-beam type, employing a construction similar to that shown in Fig. 8.

For these reasons the writer questions the cost comparison made by Messrs. Koon and Gearhart. It has been his experience, as indicated in the paper, that the cost of the vertical-beam reservoir compares favorably with conventional types. Table 4 shows the construction cost of several projects adjusted to January, 1942, prices using the *Engineering News-Record* (ENR) cost index. These costs seem self-explanatory.

TABLE 4.—COST DATA[a] ON VERTICAL-BEAM RESERVOIRS

Project	Contract cost[b]	Date awarded	ENR cost index	Contract cost[c]	Capacity (gallons)	Adjusted cost[d]
1	$39,750	August, 1935	93.82	$54,800	3,000,000	$18,300
2	4,375	November, 1938	112.69	5,040	120,000	42,000
4	2,710	March, 1942	129.65	2,710	60,000	45,200

[a] Costs do not include land, engineering, or inspection. [b] Cost of project No. 1 includes all piping for inlet, outlet, overflow, etc.; the cost of projects No. 2 and No. 4 does not include piping. [c] Adjusted to March, 1942. [d] Dollars per million gallons.

If construction joint spacing of greater than 20 ft is adequate, then this should be used, and may be used with the same advantage for the vertical-beam type of construction as for any of the conventional types.

The writer agrees that the use of unprotected tie rods is ill-advised, and, on the projects described, adequate means have been taken to protect them. The methods have varied, but for tie rods buried under the floor the following procedure is suggested: (1) Design the bars over size to allow for some corrosion; (2) give the bars two or more coats of good asphaltic waterproofing material and wrap them in burlap, sisal-craft, or similar material to protect the waterproofing; and (3) place and backfill the bars carefully with sand (for protection and drainage) so as to shield them by the slab placed above. These means of protection are not dissimilar to those used on steel pipe and if carefully applied and inspected will give adequate protection. However, if one is skeptical of the use of tie rods, they may be eliminated and the vertical-beam design may still be used by placing reinforcement in the top slab (middle illustration in Fig. 3(*a*)) to support the top of the wall and by using the weight of the water to resist the horizontal thrust at the bottom of the wall (bottom illustration in Fig. 3(*b*)).

Objection to the use of surface waterproofing on the inner walls of reservoirs is largely a matter of opinion; it applies equally to all types of design and need not be argued.

In conclusion the writer wishes to reaffirm his statement that the vertical-beam method of reservoir construction has been developed and tested so that its advantages and disadvantages can be established. In those instances where conditions permit its use, it has certain advantages and affords a simple and economical type of construction.

With Discussion by Messrs. J. M. Robertson, Joe W. Johnson and M. A. Selim, I. Nelidov, S. M. Woodward and J. W. Howe and C. J. Posey, and C. A. Mockmore.

Synopsis

The purpose of the project discussed herein was to make careful flow measurements under laboratory conditions, to record, and to study the phenomenon of flow around a stable curved channel.

An open channel, 18 in. wide and 10 in. deep, was built of transparent pyralin sections so they could be fitted together in combinations of tangents and curves. Motion pictures were taken of the flow phenomena as indicated by objects floated on the water surface, dragged or rolled on the stream bed, or held in suspension. The latter was accomplished by use of drops of a mixture of n. Butyl Plithalate and technical Xylol, colored with a deep red oil dye and having the same specific gravity as that of water. The water velocities were measured at various cross sections from which velocity contours were prepared.

Two different sets of assumptions were made as to the nature of the filamental velocities of flow around a bend, and a mathematical analysis was made of the streamlines, accelerations, and velocity components by use of the laws of hydrodynamics.

The Laboratory Experiments

Complications are inherent with the flow of water in any channel where the particles of water are forced to undergo a general change in direction. If there were streamline flow of equal filament velocities at the entrance to the bend and if friction could be eliminated so the water would act as a perfect fluid, no spiral motion could develop. The two principal causes of spiral flow in either closed or open channels are:

(*a*) The existence of friction on the channel walls, resulting in higher filamental velocities near the center of the channel than near the walls; and

(*b*) The centrifugal force required to deflect the particles of water from straight-line motion.

The existence of a condition of spiral flow around bends in open channels was first enunciated by Prof. James Thomson[2] of England in 1876.

A study of the flow conditions in the bend of a natural stream would involve many complexities, not only because of the difficulty in obtaining accurate measurements of the filamental velocities at specified points in a large stream, but also because of the many irregularities in, and the instability of, the stream bed. The laboratory is the most logical place, therefore, to study such fundamentals.

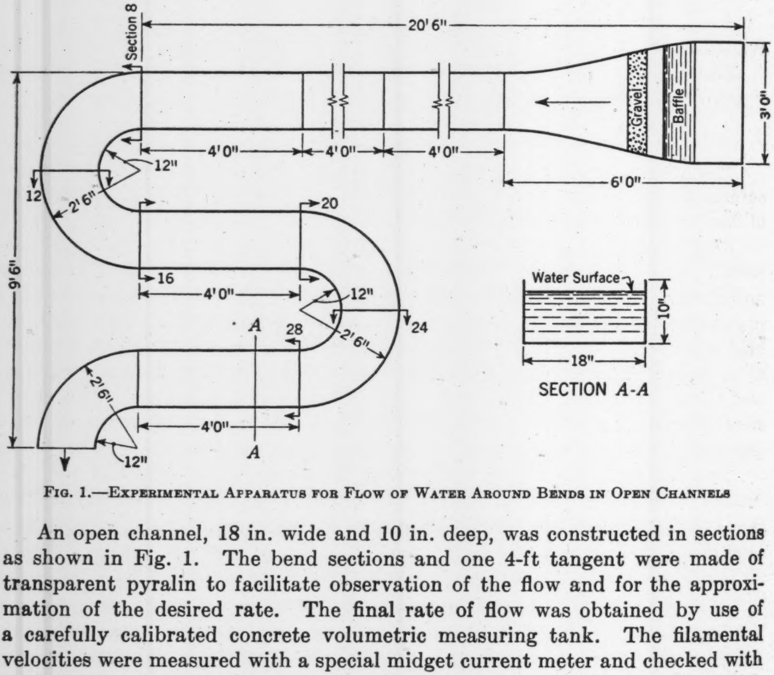

FIG. 1.—EXPERIMENTAL APPARATUS FOR FLOW OF WATER AROUND BENDS IN OPEN CHANNELS

An open channel, 18 in. wide and 10 in. deep, was constructed in sections as shown in Fig. 1. The bend sections and one 4-ft tangent were made of transparent pyralin to facilitate observation of the flow and for the approximation of the desired rate. The final rate of flow was obtained by use of a carefully calibrated concrete volumetric measuring tank. The filamental velocities were measured with a special midget current meter and checked with a pitot tube, the latter being one used in numerous other experiments, which had been carefully calibrated.[3,4,5]

The channel was set on a slope of 0.005% and the depth of the water was controlled by a tail gate at the outlet of the channel. In some experiments the gate caused a backwater curve which gave a different depth of water at each section of the channel, but this was not of enough consequence to require its elimination.

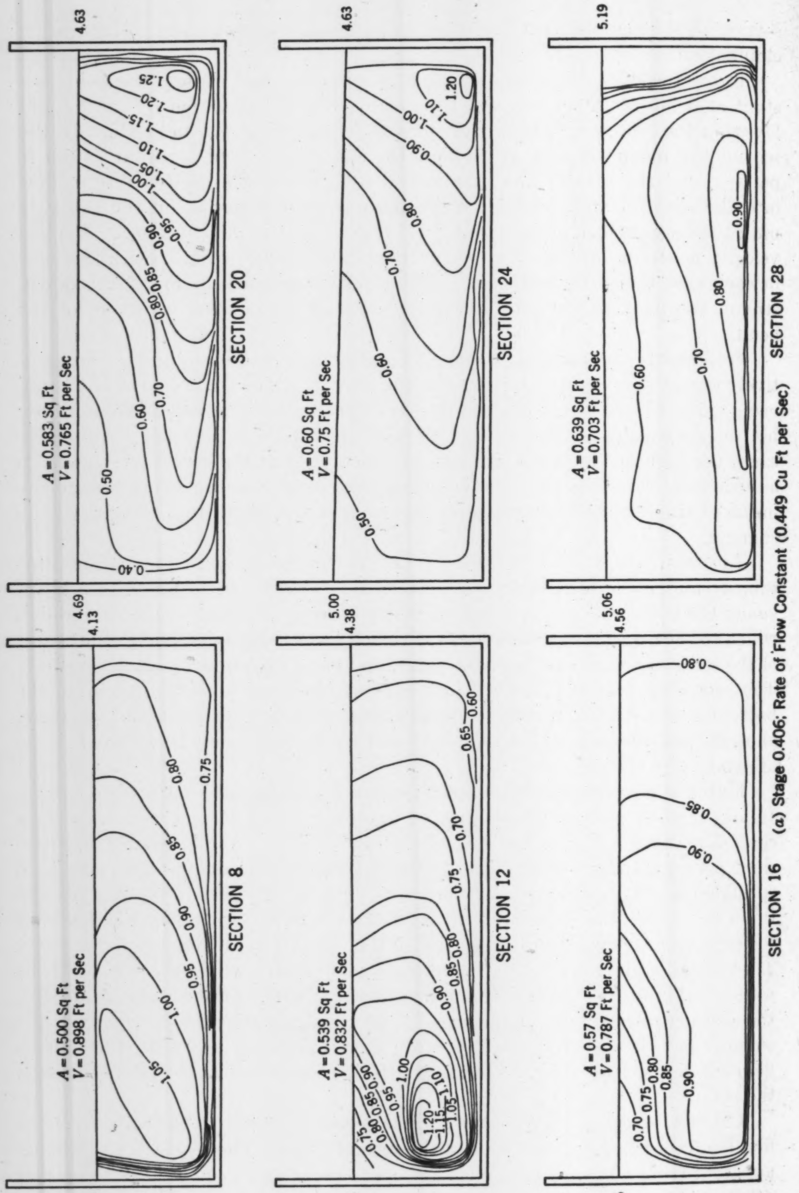
Two series of tests were conducted. In one the rate of flow was held constant at 0.449 cu ft per sec, and the mean velocity was varied by raising and lowering the water surface in the channel by means of the tail gate. In the second the mean velocity at Section 16, Fig. 1, was held constant at 0.5 ft per sec, and the rate of flow was varied by admitting a desired rate of flow into the channel and then adjusting the micrometer screws on the tail gate until the mean velocity as computed for Section 16 was 0.5 ft per sec. Typical velocity contours for these two experiments are shown in Fig. 2 with the view in each case facing downstream. All velocities recorded in Fig. 2 are downstream components, tangent to circles concentric with the curvature of the bend.

Preliminary to each test considerable effort was made to obtain a comparatively even velocity distribution over the section at the beginning of the bend, using various kinds of screens and floats at the channel inlet below the weir box; but in every stage of the flow the effect of the bend was reflected upstream to cause the highest filamental velocities to occur, not at the center of the stream as ordinarily would be the case in a straight channel, but somewhat toward the inside of the bend, depending upon the ratio of the width to the depth of the channel.

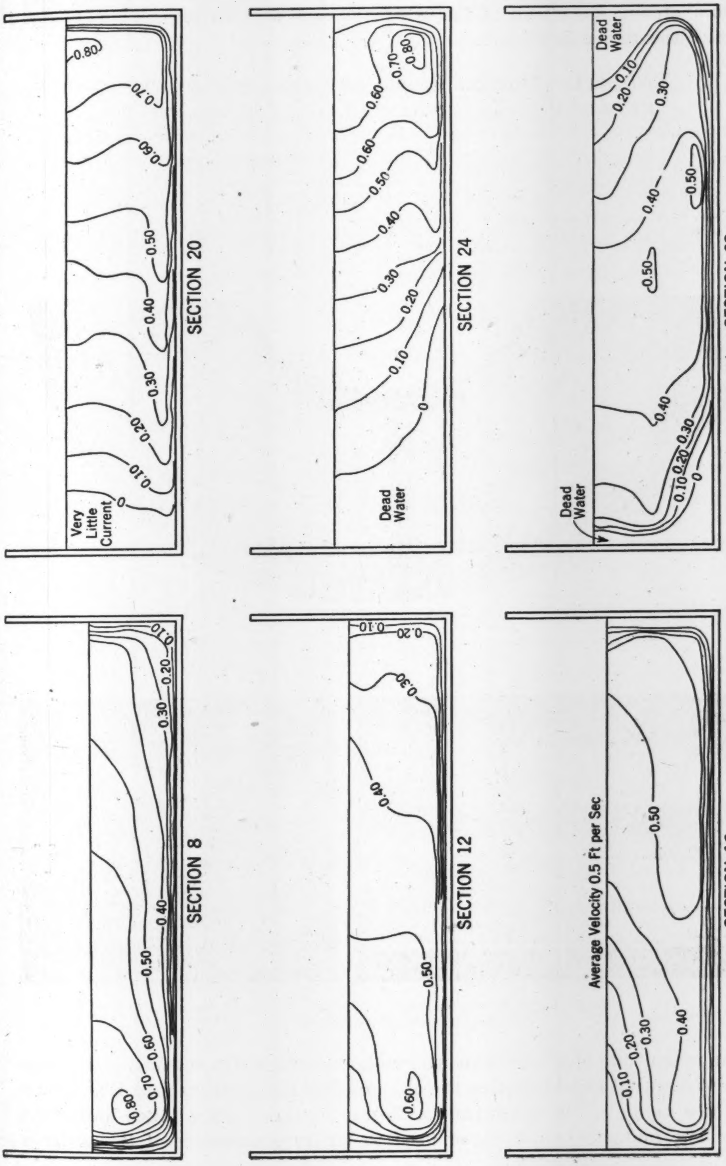
To obtain the data for velocity contours such as those in Fig. 2, the pitot tube or midget current meter was placed in a clamp and fastened to a beam across the top of the channel. Five verticals were selected as suitable through which to raise and lower the meter for velocity measurements, one at the center of the stream, one at each quarter point, and two at 0.5 in. from each side-wall. The procedure was as follows: The meter was lowered to within 0.5 in. of the bottom of the stream, a velocity measurement taken, then raised 0.5 in. more, another measurement taken, etc. The stage heights were all referred to an arbitrary zero datum.

Fig. 3 is a composite photograph made by taking several frames from a 16-mm motion picture of the first or upstream bend when the average flow conditions were as shown for Stage 0.600, in Table 1. Some crystals of potassium permanganate, which formed dark patches in the photograph, had been sprinkled on the bottom of the channel. The broken lines follow the path of the water along the extreme bottom of the channel. It will be evident that the streamlines crossed the center line of the channel at an angle of 45° or more. The unbroken lines are the paths taken by confetti strewn on the surface of the water, and indicate that the streamlines on the surface of the water edged across the channel toward the outside wall. The average downstream velocity in the channel in this case was slightly more than 0.5 ft per sec, with the highest filamental velocities near the inside wall and about one fourth the way around the bend.

Confetti strewn on the water surface seemed to edge to the outside of the first bend, but hugged the inside of the second bend. The reason for this is not apparent from a study of the velocity contours (Fig. 2), but the cause may be attributed to the short tangent between the two bends. If the tangent had



(a) Stage 0.406; Rate of Flow Constant (0.449 Cu Ft per Sec)



(*b*) Stage 0.030; Mean Velocity Constant (0.5 Ft per Sec)

FIG. 2.—TYPICAL VELOCITY CONTOURS

been longer, perhaps the surface currents of the second bend would have had time to overcome the effects of the upstream bend and perform as did the surface velocities in the first bend.

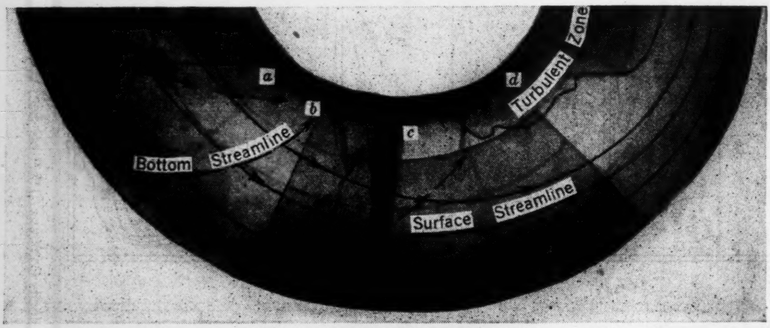

FIG. 3.—COMPOSITE PICTURE MADE FROM SEVERAL FRAMES OF A 16-MM MOTION PICTURE FLOW AROUND BEND

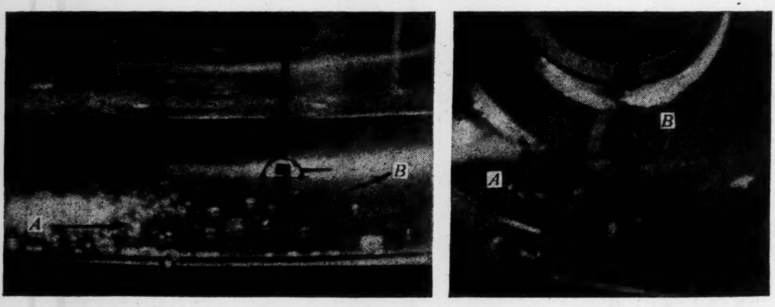

FIG. 4.—RICE GRAINS MOVED RAPIDLY ACROSS THE CHANNEL FROM A TO B, WHERE A BAR WAS FORMED

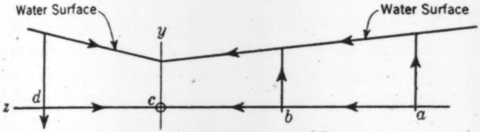
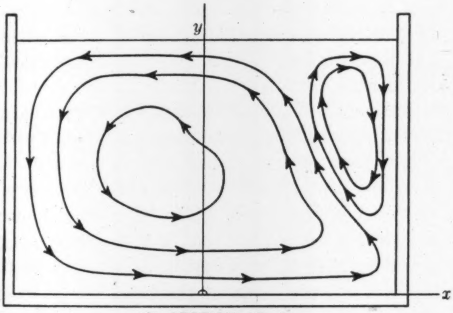
The magnitude of the bottom streamline velocities was considerable. Rice grains were swept quickly across the channel (see Fig. 4) from A to B to form a bar. The views in Fig. 4 are from a 16-mm motion picture taken during the tests. The midget current meter used to measure velocities of the water is shown.

On the convex bank in the last half of both bends there existed (see Figs. 2, 3, and 4) regions of unsteady flow in which, at times, the water actually moved upstream. At slightly more than halfway around the bend and above mid-depth the streamlines appeared to leave the inside wall of the channel. This is indicated by the darkened region of turbulent water in Fig. 3, caused by the accumulation of dissolved potassium permanganate being swept along by the streamlines nearest the bottom of the channel.

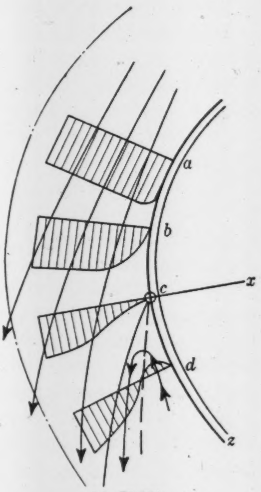
If, for the moment, the velocity component of a thin layer of fluid along the water surface in the vicinity of a, Fig. 5, is considered, it will be apparent that particles not only are moving downstream but also are edging toward the outside of the bend. Then as the particles pass on to c they experience a kind of diverging channel effect, and at d the streamlines diverge from the inside wall causing a backflow somewhat as shown. This effect was admirably demonstrated by filling the channel with still water, liberally covering the stream bed with water-soaked sawdust, and suddenly opening the tail gate wide. As the water accelerated, spiral flow developed, and the finely divided sawdust particles were carried along the bottom of the channel to the region of d, Fig. 5, where they were churned about violently in the turbulent eddy. The sawdust was then replaced with crystals of potassium permanganate, and the colored water followed the same pattern as the transported sawdust (Fig. 3).



(a) ELEVATION



(b) SECTION AT d



(c) PLAN

FIG. 5.—DEVELOPMENT OF TURBULENCE AT INSIDE OF BEND

In the lower half of the section at d, Fig. 5, the water particles had a velocity component toward the inside of the bend. This prevented the region of turbulence from developing to the same extent as it did nearer the water surface. The velocity contours (Fig. 2) give evidence of this phenomenon.

To gain information on the nature of the streamlines around the bend, use was made of a mixture of n. Butyl Plithalate and technical Xylol colored with a deep red oil dye and having the same specific gravity as water. The mixture was admitted into the stream through capillary tubes, and it came from the tubes in globules about the size of a small pea, providing a ready means of tracing the streamlines. Motion pictures were taken giving an excellent record of the existence, extent, and nature of the spiral flow. When the globules passed the section halfway around the bend and happened to be along the bottom of the channel and midway between the side-walls, their path crossed the center line of the channel at an angle of about 45°, indicating a strong current toward the convex or inner bank of the stream.

Floats consisting of ⅜-in. hedgewood cubes boiled in paraffin and marked with white crosses for identification were used to study the angular velocity of the water surface. Although the blocks showed an angular velocity about the vertical axis only, they indicated that, if an open channel turns to the left, the cubes in general take a rotational motion in the opposite direction, except in cases where a cube was trapped in the region of turbulence, such as near d, Fig. 5.

The motion of rice grains, shoved along the bottom of the channel, or chemical globules held in suspension by the water, progressed with an accelerated velocity from the outside of the bend toward the center of the channel and then decelerated as they approached the inside of the bend.

It is difficult to make any comparison of the streamlines followed by a particle of water starting near the outside at the entrance of the bend with the streamlines of a particle starting near the inside wall at the entrance of the bend because of the differences in filamental velocities and in the lengths of path. A particle starting at the entrance of the bend and on the water surface near the outside wall would move downstream slowly with a gradual lowering below the water surface; after reaching about mid-depth would accelerate toward the center of the channel; when halfway around the bend would cross the center line near the bottom of the channel at an angle of nearly 45°; and would end in the turbulent region. A particle starting at the entrance of the bend and on the water surface near the inside wall would move swiftly downstream with a strong velocity component outward, upon approaching the outside wall would gradually be lowered below the water surface, and would leave the bend near the bottom of the channel. On the average the liquid completed half a turn of the spiral in flowing around the 180° bend. However, the time required for the different particles to move through their allotted courses differed considerably, the shorter period being for those starting near the inside wall.

The transverse profile of the water surface at Section 12, Stage 0.406 (Fig. 2(*a*)), shows that the water is higher at the outside wall than at the inside wall. This condition, due to the centrifugal force of the water flowing around the bend, is not enough in itself to induce the spiral flow, but it is one of the two essential conditions, the other being a difference between the filamental velocities of the water near the surface and near the bottom of the channel.

NOMENCLATURE

The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

THEORY OF SPIRAL FLOW

The theory of the induced spiral has been discussed admirably by Sherman M. Woodward,[6] Hon. M. Am. Soc. C. E., whose reasoning may be explained by reference to Fig. 6. If the layer of water E–F moves in a curve, a centrifugal force of

$$F = \frac{m\,V^2}{r} \qquad (1)$$

must be directed toward the center of curvature. In Eq. 1, m is the mass of the water; V, the velocity in feet per second; and r, the radius of curvature. The excess of pressure on the face D–H over that on C–G causes the water to be deflected toward the center of curvature on the side toward A. This excess of pressure can exist only when the water surface at D is higher than at C. The layer near the bottom G–H has a lower velocity than the central layer E–F. Since the pressure difference between F and E is the same as that between G and H, it follows that the layer G–H has a shorter radius of curvature than the layer E–F. A spiral flow inevitably results, in this case clockwise when facing downstream. If the velocity of the layer E–F were lower than that of G–H, the spiral would be counterclockwise.

Since the vertical curve of the velocity variation approximates a parabola in shape, it is natural that the crosscurrents of the spiral be most pronounced near the bottom of the stream. At Section 12, Stage 0.406, the water surface at the outside and inside of the bend had a difference of elevation of 0.13 in. This is sufficient to induce toward the inside of the bend a theoretical velocity of 0.8 ft per sec, which is nearly as large as the average downstream velocity in the section as a whole. Friction losses greatly reduce the theoretical velocity,

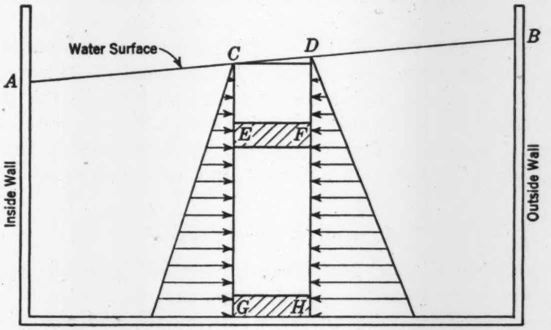


FIG. 6.—CROSS SECTION OF A BEND OF OPEN CHANNEL, FACING DOWNSTREAM

but the motion pictures taken verify the existence of a crosscurrent throughout the entire 180° bend, with the most pronounced crosscurrents near the very bottom of the stream.

[6] "Hydraulics of the Miami Flood Control Project," by S. M. Woodward, *Technical Reports*, Miami Conservancy Dist., Dayton, Ohio, Pt. VII, 1920, p. 264.

If the channel under consideration happens to be rather wide and comparatively shallow, if the water is flowing through a bend, such as may exist in a natural river or model of a river, and if it encounters channel irregularities, there undoubtedly will be localized turbulence which may tend to distort the spiral flow pattern. The localized turbulence and eddy currents in such a channel may so obscure the spiral flow pattern as to cause doubt in the minds of some as to possibility of its existence in the bend of any open channel.[7] However, if the essential driving forces exist at a bend in the stream, with higher downstream velocities near the water surface than near the stream bed, a general spiral motion as first enunciated by Thomson[2] is inevitable. A careful weighing of the basic cause of the spiral will usually suffice to convince the skeptic.[8]

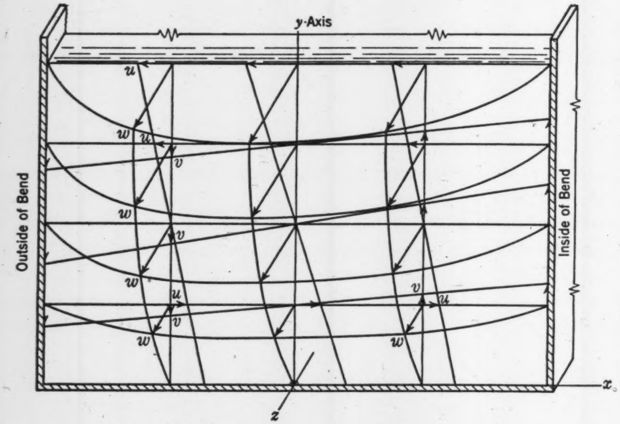

FIG. 7.—CHANNEL SECTION SHOWING SOLID OF FLOW AND ASSUMED VELOCITY COMPONENTS

MATHEMATICAL ANALYSIS

Suppose an open channel of rectangular section be considered, and that assumptions are made regarding the u-component, v-component, and w-component of the velocity parallel to the x-axis, y-axis, and z-axis as shown in Fig. 7 for a frictionless fluid as follows:

1. Parabolic variation of the u-component of the velocity, starting with zero at each side-wall and becoming a maximum on the y-axis midway between the two side-walls. Straight-line variation of the u-component, starting with

zero at mid-depth of the channel and becoming a maximum at top and bottom of channel, with opposite signs.

2. Straight-line variation of the v-component of the velocity, starting with zero on the y-axis and becoming a maximum at each side-wall, with opposite signs. Parabolic variation of the v-component starting with zero at top and bottom of channel, with a maximum value at mid-depth.

3. Parabolic variation of w-component of the velocity, starting with zero at the bottom of the channel and becoming a maximum at the water surface. Parabolic variation of w-component, starting with zero at each side-wall and becoming a maximum on the y-axis midway between the two side-walls.

Then, if b and d, respectively, represent the breadth of channel and depth of water, the velocity components at a particular cross section of the channel may be written in terms of x, y, b, d, and certain coefficients, which in this discussion will be called k_u, k_v, and k_w, for the u-component, v-component, and w-component of the velocity. Referring to Fig. 8,

$$u = k_1 k_2 \left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right) = k_u \left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right) \ldots\ldots (2a)$$

$$v = k_3 x \left[k_4 \frac{d^2}{4} - k_4 \left(\frac{d}{2} - y\right)^2 \right] = k_3 k_4 x (y d - y^2) = k_v x (y d - y^2) \ldots (2b)$$

and

$$w = k_5 \left(\frac{b^2}{4} - x^2\right) k_6 (2 y d - y^2) = k_w \left(\frac{b^2}{4} - x^2\right)(2 y d - y^2) \ldots (2c)$$

In Eqs. 2, k_u and k_v have dimensions of $L^{-2} T^{-1}$, and k_w has dimensions of $L^{-3} T^{-1}$. Assuming for simplicity that $k_u = k_v = k_w = 1$, Eqs. 2 become

$$u = \left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right) \ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

$$v = x (y d - y^2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

and

$$w = \left(\frac{b^2}{4} - x^2\right)(2 y d - y^2) \ldots\ldots\ldots\ldots\ldots\ldots (3c)$$

Streamlines.—If streamlines are defined as curves the tangents to which everywhere give the direction in which the fluid is moving, then the equation of the streamlines is[9] $\frac{dx}{u} = \frac{dy}{v} = \frac{dz}{w}$, and

$$\frac{dx}{\left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right)} = \frac{dy}{x (y d - y^2)} \ldots\ldots\ldots\ldots\ldots (4a)$$

Separating terms and integrating,

$$\log \left(\frac{b^2}{4} - x^2\right) = - \log (y d - y^2) + C_1 \ldots\ldots\ldots\ldots (4b)$$

---

[9] "An Introduction to Mathematical Physics," by R. A. Houstoun, Longmans, Green, 1925, Chapter II.

or

$$\left(\frac{b^2}{4} - x^2\right)(y\,d - y^2) = C \tag{5}$$

Eq. 5 should be the formula of the streamlines as projected on the x–y plane, which is the plane of the channel cross section. For the y–z plane,

$$\frac{dz}{\left(\frac{b^2}{4} - x^2\right)(2\,y\,d - y^2)} = \frac{dy}{x\,(y\,d - y^2)} \tag{6a}$$

but, from Eq. 5,

$$x = \left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5} \tag{6b}$$

then

$$\frac{dz}{\left(\frac{C}{y\,d - y^2}\right)(2\,y\,d - y^2)} = \frac{dy}{\left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}(y\,d - y^2)} \tag{6c}$$

and

$$z = \int \frac{C\,(2\,y\,d - y^2)\,dy}{\left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}(y\,d - y^2)^2} + C_2 \tag{7a}$$

If the coefficients k_v and k_w are retained, and Eq. 7*a* is made a definite integral,

$$z = \frac{k_w}{k_v}\int \frac{C\,(2\,y\,d - y^2)\,dy}{\left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}(y\,d - y^2)^2} \tag{7b}$$

Eq. 7*b* may be evaluated as follows:
First step: Simple reductions put the integral in the form:

$$z = \frac{k_w\,C}{k_v}\int \frac{(2\,d - y)\,dy}{(d - y)\sqrt{(y\,d - y^2)\left[\frac{b^2}{4}(y\,d - y^2) - C\right]}} \tag{8a}$$

Second step: Let $y = \left(\frac{d}{2}\right)(1 + s)$; $k^2 = 1 - \left(\frac{16\,C}{b^2\,d^2}\right)$; and $M = \frac{4\,k_w\,C}{k_v\,b\,d}$.
Then

$$z = M\int \frac{(3 - s)\,ds}{(1 - s)\sqrt{(1 - s^2)(k^2 - s^2)}} \tag{8b}$$

Third step: Break up the integrand in three terms as follows:

$$\frac{3 - s}{(1 - s)\sqrt{(1 - s^2)(k^2 - s^2)}} = \frac{1}{\sqrt{(1 - s^2)(k^2 - s^2)}} + \frac{2}{1 - k^2}\sqrt{\frac{1 - s^2}{k^2 - s^2}} - 2\,\frac{d}{ds}\left[\frac{\sqrt{(1 - s^2)(k^2 - s^2)}}{(1 - k^2)(1 - s)}\right] \tag{8c}$$

This step can be verified by differentiating the right-hand term of Eq. 8*b* as indicated, reducing all terms to a common denominator and combining. Fourth step: From Eqs. 8*b* and 8*c*,

$$z = M\left[\int \frac{ds}{\sqrt{(1-s^2)(k^2-s^2)}} + \frac{2}{1-k^2}\int\sqrt{\frac{1-s^2}{k^2-s^2}}\,ds - 2\,\frac{\sqrt{(1-s^2)(k^2-s^2)}}{(1-k^2)(1-s)}\right] \ldots\ldots\ldots (8d)$$

Fifth step: In the two integrals on the right in Eq. 8*d*, make $s = k \sin\phi$. Then

$$z = M\left[\int \frac{d\phi}{\sqrt{1-k^2\sin^2\phi}} + \frac{2}{1-k^2}\int \sqrt{1-k^2\sin^2\phi}\,d\phi - \frac{2\sqrt{(1-s^2)(k^2-s^2)}}{(1-k^2)(1-s)}\right] \ldots\ldots\ldots (8e)$$

The two integrals are now the standard elliptic integrals of the first and second kind, respectively. Hence

$$z = M\left[F(\phi,k) + \frac{2}{1-k^2}E(\phi,k) - \frac{2\sqrt{(1-s^2)(k^2-s^2)}}{(1-k^2)(1-s)}\right] + C_2 \ldots (9)$$

in which C_2 is the constant of integration.

To compute values of y and z the best method is to use ϕ as a parameter. Then, since $s = k \sin\phi$, Eq. 9 becomes

$$y = \frac{\sqrt{b^2 d^2 - 16\,C}}{2\,b}\sin\phi + \frac{d}{2} \ldots\ldots\ldots (10)$$

Then y and z are calculated[10] from Eqs. 9 and 10 respectively, using tables of $F(\phi,k)$ and $E(\phi,k)$. The streamlines have been plotted in Fig. 9, showing three views—section, plan, and elevation. Here the value $k_v = k_w = 1$ was used, merely to determine the curve forms, since any other relationship between k_v and k_w would only change the distance that a particle would have to move downstream to complete one cycle of the curves, but would not change their general shape.

Angular Velocity.—According to the laws of hydrodynamics the components of the angular velocity, ξ, η, and ζ, about the x-axis, y-axis, and z-axis are, assuming time does not affect the velocities at a given section:

$$\xi = \frac{1}{2}\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right) = (d-y)\left(\frac{b^2}{4} - x^2\right) \ldots\ldots\ldots (11a)$$

$$\eta = \frac{1}{2}\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right) = x\,(2\,y\,d - y^2) \ldots\ldots\ldots (11b)$$

and

$$\zeta = \frac{1}{2}\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) = \frac{1}{2}(y\,d - y^2) + \left(\frac{b^2}{4} - x^2\right) \ldots\ldots\ldots (11c)$$

---

[10] "Formules et Tables Numeriques aux Fonctions Circulaires, Hyperboliques, Elliptiques," by L. Potin, 1925, pp. 753–827.

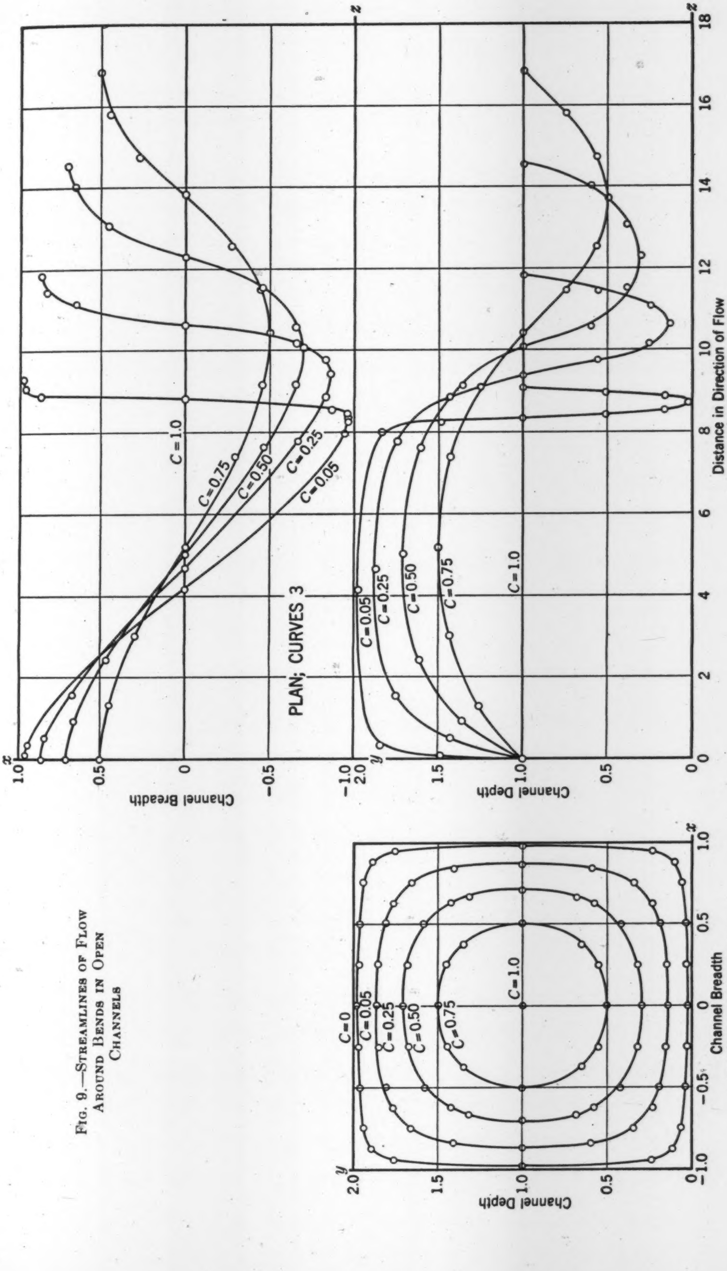

Fig. 9.—Streamlines of Flow Around Bends in Open Channels

Then the angular velocity in radians per second is:

$$\omega = \sqrt{\xi^2 + \eta^2 + \zeta^2}$$

$$= \sqrt{\left[(d-y)\left(\frac{b^2}{4}-x^2\right)\right]^2 + [x\,(2\,y\,d-y^2)]^2 + \left[\frac{1}{2}(y\,d-y^2) + \left(\frac{b^2}{4}-x^2\right)\right]^2} \quad ..(12)$$

A check on the accuracy of Eq. 12 may be had by noting that the divergence of the angular velocity must be zero: That is, a divergence of

$$\omega = \frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} + \frac{\partial \zeta}{\partial z} = 0 = \frac{\partial}{\partial x}\left[\,(d-y)\left(\frac{b^2}{4}-x^2\right)\right] + \frac{\partial}{\partial y}[x\,(2\,y\,d-y^2)],$$

or

$$\omega = -2\,x\,(d-y) + 2\,x\,(d-y) = 0 \ldots\ldots\ldots\ldots\ldots(13)$$

In Eq. 12 it should be noted that the η-component is not affected by the breadth of the channel.

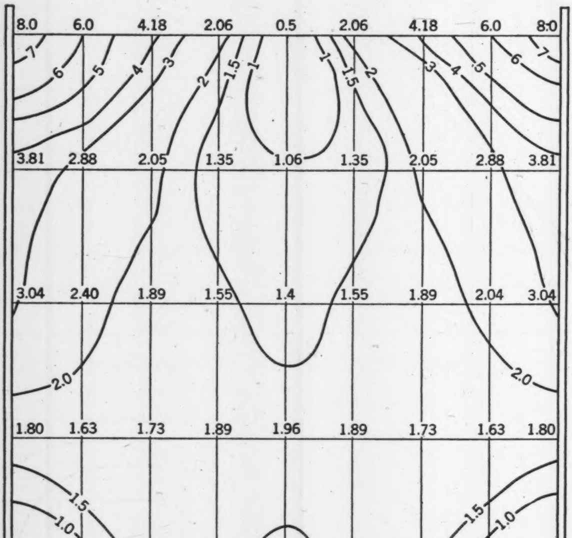

FIG. 10.—LINES OF EQUAL ANGULAR VELOCITY

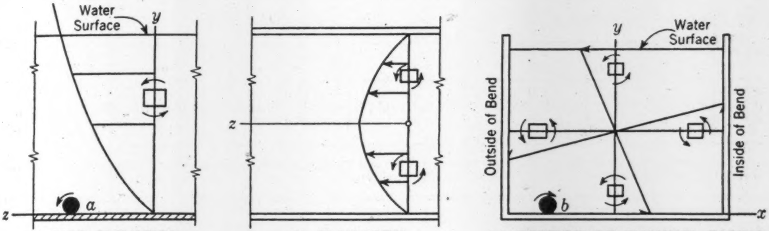
Fig. 10 shows lines of equal angular velocity in the channel section, assuming $b = d = 2$, and $k_u = k_v = k_w = 1$. It is worthy of note that at values of $y = \frac{d}{4}$, the vorticity is fairly uniform all across the channel. The symmetry of the diagram is due to the original assumptions as to velocity components.

The direction of rotation of the components of the angular velocity can be seen by reference to Fig. 11. The direction of rotation in the y–z and y–x planes is always the same regardless of what point in the section is selected, whereas rotation in the z–x plane changes direction as a particle moves from the inside half of the bend through the center of the channel to the outside half of the bend.



(*a*) SIDE ELEVATION y - z PLANE (*b*) PLAN VIEW z - x PLANE (*c*) SECTION OF CHANNEL FACING UPSTREAM, y - x PLANE

FIG. 11.—DIRECTION OF ROTATION OF ANGULAR VELOCITY COMPONENTS

Acceleration.—Components of the acceleration parallel to the x-axis, y-axis, and z-axis are given by the equations:

$$a_x = u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z} = -2x\left(\frac{d}{2} - y\right)^2\left(\frac{b^2}{4} - x^2\right) - x\left(\frac{b^2}{4} - x^2\right)(y\,d - y^2) \qquad \text{(14a)}$$

$$a_y = u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + w\frac{\partial v}{\partial z} = \left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right)(y\,d - y^2) + x^2(y\,d - y^2)(d - 2y) \qquad \text{(14b)}$$

and

$$a_z = u\frac{\partial w}{\partial x} + v\frac{\partial w}{\partial y} + w\frac{\partial w}{\partial z} = -2x(2y\,d - y^2)\left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right) + 2xy(d - y)^2\left(\frac{b^2}{4} - x^2\right) \qquad \text{(14c)}$$

$$A = \sqrt{a^2_x + a^2_y + a^2_z} = \left\{\left[-2x\left(\frac{d}{2} - y\right)^2\left(\frac{b^2}{4} - x^2\right) - x\left(\frac{b^2}{4} - x^2\right)(y\,d - y^2)\right]^2 + \left[\left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right)(y\,d - y^2) + x^2(y\,d - y^2)(d - 2y)\right]^2 + \left[-2x(2y\,d - y^2)\left(\frac{d}{2} - y\right)\left(\frac{b^2}{4} - x^2\right) + 2xy(d - y)^2\left(\frac{b^2}{4} - x^2\right)\right]^2\right\}^{0.5} \qquad \text{(15)}$$

Table 2 shows components of the acceleration parallel to the x-axis, y-axis, and z-axis for different values of x, y, and z in terms of b and d, assuming

$k_u = k_v = k_w = 1$. It should be noted that, at all points in the section, a_x varies as $b^3\,d^2$; a_y varies as $b^2\,d^3$; and a_z varies as $b^3\,d^3$. This is significant where, as in most natural streams, breadth is greater than depth, and hence the acceleration across the channel and parallel to the x-axis is much greater than that in the vertical direction parallel to the y-axis. Likewise, the maximum u-component of the velocity, parallel to the x-axis, would exceed the v-component, parallel to the y-axis, and be in direct ratio of width to depth of stream.

TABLE 2.—COMPONENTS OF ACCELERATION, a,

Values of x[a]	$y = 1.00\,d$			$y = 0.75\,d$			
	a_x	a_y	a_z	a_x	a_y	a_z	a_x
$0.50\,b$	0	0	0	0	$-3\,b^2\,d^3/128$	0	0
$0.25\,b$	$3\,b^3\,d^2/128$[b]	0	$-3\,b^3\,d^3/64$[b]	$-3\,b^3\,d^2/1{,}024$[b]	$-33\,b^2\,d^3/1{,}024$	$-24\,b^3\,d^3/1{,}024$[b]	$3\,b^3\,d^2/256$[b]
0[c]	0	0	0	0	$-3\,b^2\,d^3/256$	0	0

[a] Values of x in terms of channel width, b. [b] All values in this table are for the outside half of the indicated by the footnote index. [c] Center line of channel.

On the outside half of the channel the velocity components parallel to the x-axis, and in the lower half of the section, are directed toward the inside of the bend and are increasing in magnitude as the particle moves toward the center of the channel. If a piece of gravel or sand should start moving along the bed of the stream in this vicinity, it would tend to continue and, after passing the middle of the stream, would tend to be stopped due to the decelerating components of the filamental velocities directed toward the inside of the bend.

The components of the angular velocity are helpful in understanding the movement of detritus along the bed of the stream. If, in Eq. 12, y is taken as zero, the angular velocity becomes:

$$\omega = \sqrt{\left[d\left(\frac{b^2}{4} - x^2\right)\right]^2 + 0 + \left[\frac{1}{2}\left(\frac{b^2}{4} - x^2\right)\right]^2} \quad \ldots\ldots\ldots(16)$$

Hence, under the assumptions made, there is no tendency for the gravel on the stream bed to rotate about a vertical axis, but there are components of angular velocity about the x-axis and z-axis. The rotation about the x-axis is the same as the direction a piece of gravel would be obliged to roll along the stream bed, and, although the rotation about the z-axis, parallel to the axis of the center line of the channel (Figs. 11(a) and 11(b)), is retrograde to the direction a piece of gravel would be obliged to rotate, its magnitude varies as $\frac{b^2}{8}$ compared to $\frac{b^2\,d}{4}$ for the value of $x = 0$ at the center of the stream. When $b = d = 2$ and $k_u = k_v = k_w = 1$, the one component is four times the other in value. However, in a natural channel it is likely that the maximum cross-currents are at some distance above the bed of the stream, in which case the angular velocity would not be retrograde to the direction that a piece of gravel would roll.

The coefficients accompanying the components of the acceleration in Table 2 are based on the assumption $k_u = k_v = k_w = 1$, which is not necessarily true, although it can be shown that $k_u = k_v$, since the divergence of

channel. Values for the inside half are symmetrically similar except that the sign is changed in the cases

the velocity $= 0 = \dfrac{\partial u}{\partial x} + \dfrac{\partial v}{\partial y} + \dfrac{\partial w}{\partial z}$; and that $\dfrac{\partial}{\partial x}\left[k_u\left(\dfrac{d}{2} - y\right)\left(\dfrac{b^2}{4} - x^2\right)\right]$ $= -\dfrac{\partial}{\partial y}\left[k_v\, x\,(y\, d - y^2)\right]$; or $k_u = k_v$.

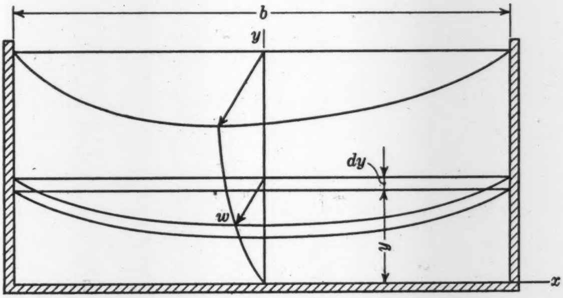

FIG. 12.—VELOCITY COMPONENT ALONG THE z-AXIS

The relation of these coefficients to k_w depends upon how far downstream a particle must move to complete a cycle of the streamlines shown in Fig. 9. However, some notion of the value of k_w may be had from the following analysis: From Fig. 12 it is apparent that when $x = 0$, $dQ = \dfrac{2}{3}\, b\, w\, dy$ $= \dfrac{2}{3}\, b\, k_w \left(\dfrac{b^2}{4} - x^2\right)(2\, y\, d - y^2)\, dy$. When $x = 0$,

$$dQ = \frac{k_w\, b^3}{6}\,(2\, y\, d - y^2)\, dy \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Integrating,

$$Q = \frac{k_w\, b^3}{6}\int_0^d (2\, y\, d - y^2)\, dy = \frac{k_w\, b^3\, d^3}{9} \ldots\ldots\ldots\ldots (18)$$

By use of Eq. 18 it is possible to evaluate k_w if the rate of flow Q, breadth of channel b, and depth of channel d are known.

At this point it is of interest to note the ratio of the maximum to the average velocity, w, in the direction of the z-axis. The maximum w-component is: When $x = 0$, and $y = d$,

$$w\,(\text{max}) = k_w \left(\frac{b^2}{4} - x^2 \right) (2\,y\,d - y^2) = \frac{k_w\,b^2\,d^2}{4} \ldots\ldots\ldots \text{(19a)}$$

$$w\,(\text{ave}) = \frac{Q}{b\,d} = \frac{k_w\,b^2\,d^2}{9} \ldots\ldots\ldots \text{(19b)}$$

and

$\dfrac{w\,(\text{max})}{w\,(\text{ave})} = \dfrac{k_w\,9\,b^2\,d^2}{k_w\,4\,b^2\,d^2} = \dfrac{9}{4} = 2.25.$ This would indicate that the maximum value of the velocity along the axis of the stream is 2.25 times as large as the average, on the basis of the assumptions made in this paper.

FREE VORTEX FLOW

Now suppose the w-component of the velocity complies more nearly with the law of a free vortex as shown in Fig. 13. Referring to Figs. 13(*b*) and 13(*c*), $k_7\,d^2 - k_7\,(d - y)^2 = k_7\,(2\,y\,d - y^2)$ and $w_i\,r_i = w_o\,r_o =$ a constant.

At the water surface

$$w = \frac{k_8}{r} \ldots\ldots\ldots \text{(20a)}$$

and at any point—

$$w = \frac{k_7\,k_8\,(2\,y\,d - y^2)}{r_c - x} = \frac{k_w\,(2\,y\,d - y^2)}{r_c - x} = \frac{k_w\,(2\,y\,d - y^2)}{1 + \frac{b}{2} - x} \ldots\ldots \text{(20b)}$$

If u and v remain the same as before, and $k_u = k_v = k_w = 1$, the components of the filamental velocities parallel to the x-axis, y-axis, and z-axis will be:

$$u = \left(\frac{d}{2} - y \right) \left(\frac{b^2}{4} - x^2 \right) \ldots\ldots\ldots \text{(21a)}$$

$$v = x\,(y\,d - y^2) \ldots\ldots\ldots \text{(21b)}$$

$$w = \frac{2\,y\,d - y^2}{1 + \frac{b}{2} - x} \ldots\ldots\ldots \text{(21c)}$$

Streamlines.—In the x–y plane the streamlines are the same as those computed under the first assumptions. The general equation is obtained as follows:

$$\frac{dz}{2\,y\,d - y^2} \div \left(1 + \frac{b}{2} - x \right) = \frac{dy}{x\,(y\,d - y^2)} \ldots\ldots\ldots \text{(22a)}$$

and

$$dz = \frac{(2\,d - y)\,dy}{x\,(d - y) \left(1 + \frac{b}{2} - x \right)} \ldots\ldots\ldots \text{(22b)}$$

Substituting from Eq. 5, $x = \left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}$ and

$$z = \int \frac{(2\,d - y)\,dy}{\left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}(d - y)\left[1 + \frac{b}{2} - \left(\frac{b^2}{4} - \frac{C}{y\,d - y^2}\right)^{0.5}\right]} + C_3 \ldots (23)$$

FIG. 13.—FLOW CONDITIONS FOR FREE VORTEX FLOW

It appears difficult to evaluate this integral, and perhaps it is not necessary since some notion of the nature of the streamlines may be had by reference to those for the first assumptions.

Angular Velocity.—For the revised assumptions as to velocity distribution, the general equation for angular velocity becomes:

$$\omega = \sqrt{\left[\frac{d-y}{1+\frac{b}{2}-x}\right]^2 + \left\{-\frac{y}{2}\left[\frac{2\,d-y}{\left(1+\frac{b}{2}-x\right)^2}\right]\right\}^2 + \left[\frac{y}{2}(d-y)+\frac{1}{2}\left(\frac{b^2}{4}-x^2\right)\right]^2} \quad ..(24)$$

The divergence of this angular velocity was checked and found to be zero, as it should be. The component in the y–x plane is the same as under the first assumptions, and, although the component in the y–z plane is changed, its direction has not been altered. The angular velocity in the z–x plane has the same direction at all points in the section; that is, it will not change sign from one side of the channel to the other as under the first assumptions.

Acceleration.—For the free vortex flow the acceleration becomes:

$$\begin{aligned} a = \Bigg\{ & \left[-2\,x\left(\frac{d}{2}-y\right)^2\left(\frac{b^2}{4}-x^2\right) - x\left(\frac{b^2}{4}-x^2\right)(y\,d-y^2)\right]^2 \\ & + \left[\left(\frac{d}{2}-y\right)\left(\frac{b^2}{4}-x^2\right)(y\,d-y^2) + x^2\,(y\,d-y^2)\,(d-2\,y)\right]^2 \\ & + \left[\frac{\left(\frac{d}{2}-y\right)\left(\frac{b^2}{4}-x^2\right)(2\,y\,d-y^2)}{\left(1+\frac{b}{2}-x\right)^2} + \frac{2\,x\,(y\,d-y^2)\,(d-y)}{1+\frac{b}{2}-x}\right]^2\Bigg\}^{0.5} \quad . (25) \end{aligned}$$

The components of the acceleration parallel the x-axis and y-axis, and, as given by Eq. 25, have not been changed over what they were under the original assumptions; hence the projection of the streamlines on the z–y plane is the same as that shown in Fig. 9. The z-component of the acceleration, parallel to the axis of the stream, does not now have as large values as before. If time and care were taken to compare velocities and accelerations as indicated by equations here developed, a suitable comparison between the streamlines of Fig. 9 and those indicated by Eq. 23 might be made.

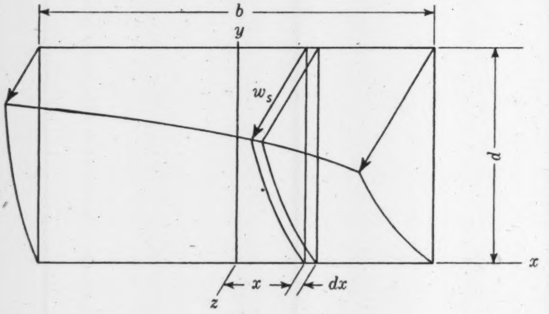

FIG. 14

It is possible to analyze the relation between the maximum and the average w-component of the velocity, similar to that under the original assumptions. If w_s is taken as the w-component of the velocity at the water surface, then (see Fig. 14):

$$dQ = \frac{2}{3}\, d\, w_s\, dx = \frac{2}{3}\, d\, k_w \left(\frac{2\,y\,d - y^2}{r_c - x}\right) dx \tag{26a}$$

When $y = d$

$$dQ = \frac{2\,k_w\,d^3}{3\,(r_c - x)}\, dx \tag{26b}$$

and

$$Q = \frac{2}{3}\, k_w\, d^3 \int_{-0.5\,b}^{0.5\,b} \frac{dx}{r_c - x} = -\,\frac{2}{3}\, k_w\, d^3 \log_e \left(\frac{2\,r_c - b}{2\,r_c + b}\right) \tag{27}$$

The maximum value of the w-component of the velocity occurs when $y = d$ and $x = \frac{b}{2}$; then

$$w = \frac{k_w\,(2\,y\,d - y^2)}{r_c - x} \tag{28a}$$

$$w\,(\max) = \frac{k_w\,d^2}{r_c - 0.5\,b} = \frac{2\,k_w\,d^2}{2\,r_c - b} \tag{28b}$$

and

$$w\,(\text{ave}) = \frac{Q}{b\,d} = -\,\log_e \frac{2\,r_c - b}{2\,r_c + b} \left(\frac{2\,k_w\,d^2}{3\,b}\right) \tag{28c}$$

Finally,

$$\frac{w\,(\max)}{w\,(\text{ave})} = \frac{-\,3\,b}{(2\,r_c - b)\log_e \dfrac{2\,r_c - b}{2\,r_c + b}} \tag{29}$$

In the laboratory experiment where $r_c = 1.75$ ft and $b = 1.5$ ft, the ratio indicated by Eq. 29 has the value of 2.457, and is about 10% higher than under the first set of assumptions as to filamental velocities. It is of interest to note that Eq. 29 is not affected by the depth of the channel, the only variables in the right-hand member being breadth of channel and radius of curvature.

Eq. 27 can be used to evaluate k_w when the rate of flow and the breadth, depth, and radius of curvature of channel are known. For the laboratory experiment when the rate of flow $Q = 0.449$ cu ft per sec, $b = 1.50$ ft, $d = 0.467$ ft, and $r_c = 1.75$ ft, k_w has the value of 7.22. Using this value of k_w, computations were made for the theoretical velocities at 0.6 d and plotted against values scaled from velocity contours obtained from laboratory data as shown in Fig. 2(a). The laboratory data were for a section of the channel taken one-half way around a 180° bend.

Some justification may be had for assuming the w-component of the filamental velocities to vary according to the law of a free vortex. (Fig. 15 shows values of the velocity scaled from Fig. 16, Section 12, Stage 0.496, at 0.60 depth, and $k_w = 7.2$.) The computed values of the velocities are higher than the actual values near the water surface, and are smaller near the bottom of the channel. This difference perhaps could have been made less by taking the origin of the parabola, Fig. 15, Section A–A, at the bottom of the channel instead of at the water surface as was done in the original assumptions; but there seems to be no really typical vertical velocity curve for all open channels,[11] and if one were to be selected for a rectangular channel in actual service it

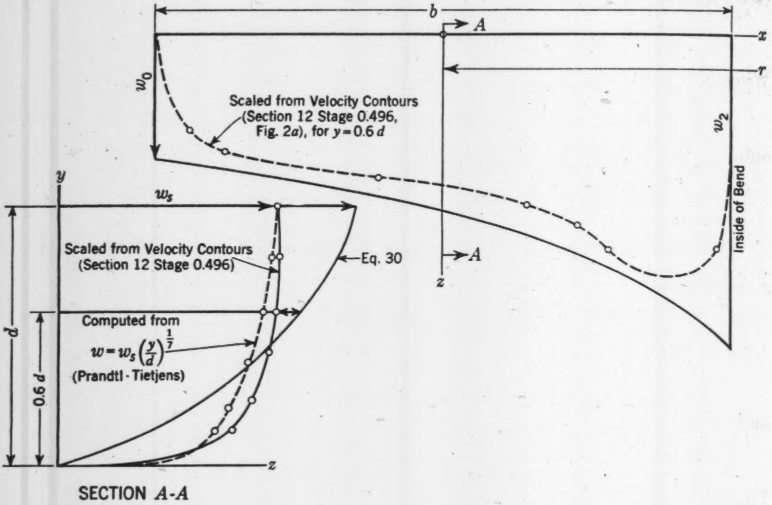

FIG. 15.—COMPARISON OF ACTUAL TO COMPUTED VALUES OF *w*-COMPONENTS OF VELOCITIES

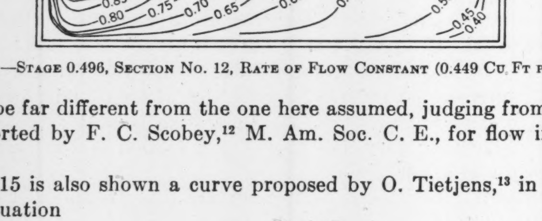

FIG. 16.—STAGE 0.496, SECTION NO. 12, RATE OF FLOW CONSTANT (0.449 CU FT PER SEC)

would not be far different from the one here assumed, judging from the actual curves reported by F. C. Scobey,[12] M. Am. Soc. C. E., for flow in irrigation canals.

In Fig. 15 is also shown a curve proposed by O. Tietjens,[13] in accordance with the equation

$$w = w_s\left(\frac{y}{d}\right)^{1/7} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

---

[11] *Water-Supply Paper No. 868-A*, U. S. Geological Survey, Plate 4.

[12] "The Flow of Water in Irrigation Canals," by Fred C. Scobey, *Bulletin No. 194*, U. S. D. A., 1915, p. 18.

[13] "Hydro- und Aeromechanik," by L. Prandtl and O. Tietjens, *Zweiter Band*, Springer, Berlin, 1931, p. 87.

Although this compares favorably with the actual velocity measurements, it does not exactly fit, and to make use of such a law for the mathematical definition of the velocity components would lead to an equation of the streamlines that would be most difficult if not impossible to evaluate.

The curve for Eq. 30, for $x = 0$, $r_c = 1.75$ ft, $d = 0.467$ ft, $b = 1.50$ ft, and $k_w = 7.2$, is also included in Fig. 15.

CONCLUSIONS

This research was undertaken as a study of the flow conditions in the bend of an open channel. Many observations have indicated that the spiral exists in the bends of both open and closed channels, and that in the latter the spiral is usually double. An attempt has been made to observe the direction and magnitude of the angular velocities of particles in suspension as the water moved through the channel bend, and to compare these with theoretical analyses made under assumed flow conditions. The observed rotation of the suspended particles behaved in general with the theoretical analysis based on the assumed conditions. The path taken by a particle on its way around a bend in an open channel is extremely complicated and varied, but in general it must follow the pattern of a spiral.

In the experimental channel the crosscurrents moving along the stream bed from outside to inside of bend were amazingly strong compared to the average velocities in the stream. Evidence of this phenomenon was recorded in a motion picture for reference.

The following conclusions seem justified by the research:

1. Spiral flow in the bends of open channels as enunciated by James Thompson[2] certainly does exist, although the spiral pattern is an exceedingly complex one.
2. The downstream components of the filamental velocities in the first half of the bend are greater near the convex bank than at the concave bank and vary across the channel in close agreement with the law of a free vortex.
3. The angular velocities and accelerations inherent to the spiral motion constitute strong contributing factors to the movement of bed load, not only in a downstream direction but toward the inside of bends.
4. At about three fourths the way around the bend there is a tendency for the development of an eddy, or slack water, along the inside bank due to the spiral motion, which is conducive to the deposition of suspended matter and the formation of a bar.

ACKNOWLEDGMENTS

Special acknowledgment is due W. E. Milne, head of the department of mathematics at Oregon State College, Corvallis, Ore., for the solution of the streamline equation, and to Alton E. Alspaugh and William B. Matlock for plotting the curves for the streamlines. The writer also wishes to give credit to Frank E. Lucas, Jun. Am. Soc. C. E., for help in the construction of the laboratory apparatus, and to all other individuals whose advice and counsel were so kindly given.

The funds for the purchase of expendable laboratory apparatus and miscellaneous materials for the project were furnished by the Engineering Foundation through J. C. Stevens, M. Am. Soc. C. E., chairman of the committee of the Society's Hydraulic Division on Hydraulic Research.

APPENDIX

NOTATION

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Hydraulics, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:[14]

a = acceleration for free vortex flow;
b = breadth of water stream;
C = constants of integration, C_1, C_2, etc.;
d = depth of stream;
F = a centrifugal force;
k = modulus of the elliptic integral: k_u, k_v, and k_w = velocity coefficients, referring to the u-component, v-component, and w-component of velocity;
L = length;
m = mass of water;
Q = rate of flow;
r = radius of curvature: r_c = radius of curvature at center of stream; r_i = inside radius; and r_o = outside radius;
T = time;
u = component of velocity, parallel to the x-axis;
V = average velocity across one given section;
v = component of velocity, parallel to the y-axis;
w = component of velocity, parallel to the z-axis;
x = lateral distance, measured parallel to the x-axis, across the channel;
y = vertical distance, measured parallel to the y-axis;
z = horizontal distance, measured parallel to the z-axis, along axis of channel;
ζ = angular velocity about the x-axis;
η = angular velocity about the y-axis;
ξ = angular velocity about the z-axis;
ϕ = amplitude of the elliptic integral;
ω = angular velocity.

DISCUSSION

J. M. ROBERTSON,[15] JUN. AM. SOC. C. E.—The conclusions reached in this paper appear to be in essential agreement with those of previous investigators. For instance, the author states (see Conclusion 2) that "The downstream components of the filamental velocities in the first half of the bend are greater near the convex bank than at the concave bank * * *." Essentially the same conclusion was reached by the late D. L. Yarnell,[16,17,18] M. Am. Soc. C. E., at the University of Iowa at Iowa City, in connection with his extensive study of the flow of water around bends in open and closed channels. In the paper in which he and Mr. Woodward report on the flow in open and closed 180° bends the following conclusions are reached:[17] "* * * with substantially uniform velocity distribution in the approach channel to the bend, the velocities of the filaments along the inside wall of the bend are increased while the velocities of the filaments along the outside wall are reduced, * * *" and, "as the water flows around a bend the effect of wall friction is to produce an unstable relation between the filaments flowing at different velocities, with the result that the filaments of highest velocity tend through a secondary circulation to drift toward the outer wall of the bend." This second statement pertains to the flow near the end of a 180° bend. In spite of information such as this, the writer can refer to several well-known books on hydraulics in which data are presented and statements are made, inferring that, as water flows around a bend, the filament of maximum velocity is always at the outside of the bend. Actually, as may be seen from the author's study, the filament of maximum velocity is initially, and, for most of the way around the bend, near the inside of the bend.

The flow of water or any fluid around a bend in an open or closed channel is affected by many factors; it is unfortunate that Professor Mockmore did not investigate more of them. Besides the primary variable of the rate of flow (or the Reynolds number) the flow conditions in a bend should depend upon the relative curvature of the bend, the shape of the channel cross section, and the length of the bend. Also, when one bend follows another, the flow conditions in the second bend are modified greatly by the relative proximity of the first bend. The writer will attempt to evaluate the effect of some of these variables on the flow in open channel bends through reference to data obtained mainly in closed conduit bends. If one keeps in mind that, at least in most respects, the flow in an open channel is similar to that in the lower half of a closed channel of twice the depth, it is not difficult to translate these observations to open channel bends, at least qualitatively.

In one part of his mathematical analysis the author assumes that the downstream component (w-component) of the velocity follows the free vortex law, according to which the velocity at any point is inversely proportional to the radius to that point. As was shown by Fig. 15, this is a good assumption. It would be expected from this law that the sharper the curvature of the bend the more pronounced would be the velocity distribution. Several years ago in connection with a study of the flow of water around bends in pipes at the Hydraulics Laboratory of the University of Illinois at Urbana, under the direction of W. M. Lansford, M. Am. Soc. C. E., the writer measured the velocity distribution in several 90°, cast-iron, flanged, bends in a 4-in. pipe line.[19] The bends were preceded by some 450 diameters of straight pipe, thus

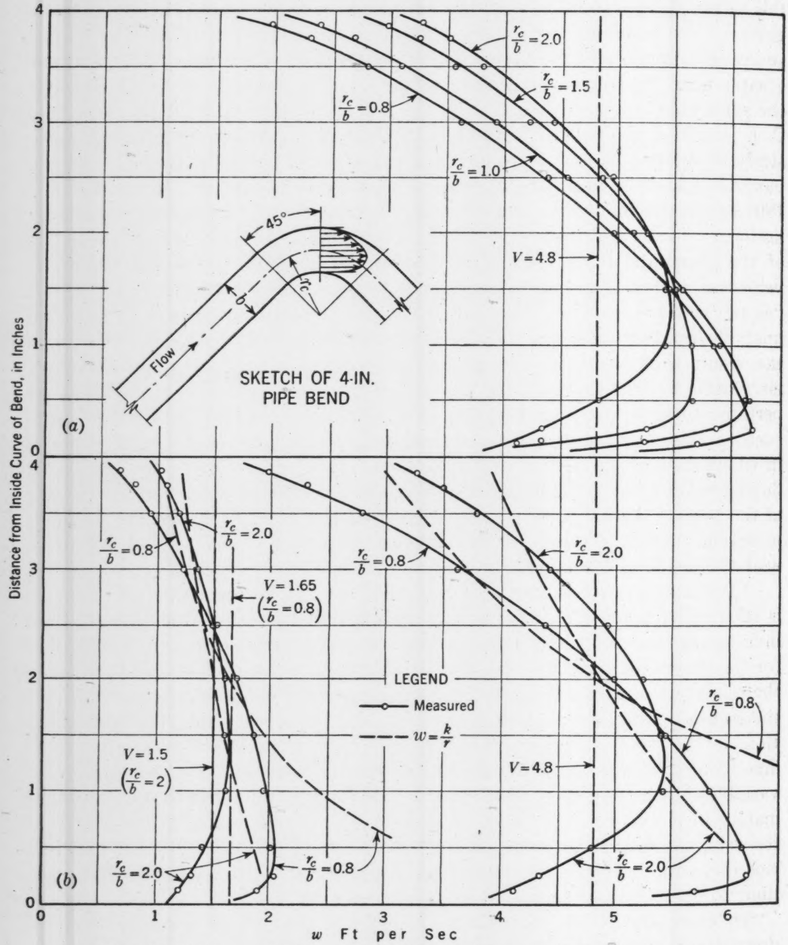

FIG. 17.—EFFECT OF CURVATURE ON VELOCITY DISTRIBUTIONS IN PIPE BENDS

assuring a normal velocity distribution above them; and the measurements were made across a diameter, 45° around the bend, in the plane of the bend. Using the ratio $\frac{r_c}{b}$ (r_c is the radius of the center line of the bend, and b is the channel breadth or pipe diameter) as indicative of the relative curvature of the bend, the curvatures of the bends studied were 0.8, 1.0, 1.5, and 2.0. Two bends of each curvature were studied. Typical velocity distributions obtained are shown in Fig. 17(*a*) for a mean flow velocity V of about 4.8 ft per sec. The effect of curvature on velocity distribution is quite apparent. A rough comparison of the results obtained with the free vortex law prediction is shown in Fig. 17(*b*) for two rates of flow in the bends of least and greatest curvatures. The constant in the free vortex law relation for each case was chosen arbitrarily so that

---

[19] "A Study of the Flow of Water Around Bends in Pipes," by J. M. Robertson, thesis for the degree of Bachelor of Science in Civil Engineering, College of Eng., Univ. of Illinois, Urbana, 1938.

$$w\,r = k = V\,r_c \qquad (31)$$

The general trends predicted by the free vortex law appear to be verified, but the actual distributions are modified greatly due to the effect of the velocity distribution in the approach pipe. In general, it appears that the sharper the curvature the greater will be the maximum velocity and the nearer the filament of maximum velocity will be to the inside of the bend.

Another case in which the curvature plays an important rôle is in connection with the superelevation of the water surface as the water flows around the bend. As the author states, this is due to the centrifugal action of the water rounding the bend. In a closed conduit this phenomenon manifests itself in a difference in pressure between the inner and outer curves of the bend or elbow. As has been shown by Professor Lansford[20] and others,[16,17,21] this difference in pressure allows the bend to be used as a flow meter. Starting with the basic force relation given by Eq. 1, the expression for this difference in pressure Δh, in feet of fluid flowing, in terms of the velocity head $\frac{V^2}{2\,g}$ in the pipe line (V is the average velocity) becomes,[6,20]

$$\Delta h = \frac{2\,b}{r_c}\,\frac{V^2}{2\,g} = K\,\frac{V^2}{2\,g} \qquad (32)$$

For a circular pipe, b is the diameter; for a rectangular channel, it is the breadth. In the study on the flow in 4-in. pipe bends previously referred to,[19] the writer verified the relation between the coefficient K in Eq. 32 and the bend curvature. The results are shown in Fig. 18. The pressure differences all were measured across a diameter 45° around the bend in the plane of the bend. The values shown for K were found to apply for velocities from 2.5 to 9.5 ft per sec. Below 2.5 ft per sec the coefficient increased somewhat, probably due to a Reynolds number effect such as is observed for other differential head meters. Also shown on this plot are data taken by Herbert Addison[21] for 4-in. and 8-in. circular cast-iron pipe bends, by Mr. Yarnell[18] for a circular 6-in. celluloid bend, by Professor Lansford[20] for various sizes of bends up to 24 in., and by Mr. Addison[21] for two cast-iron and one brass, square (b = 6 cm), closed channel bends. Considering the fact that all of these elbows and bends may not have had such ideal approach conditions as did the writer's, the agreement is excellent.

---

[20] "The Use of an Elbow in a Pipe Line for Determining the Rate of Flow in the Pipe," by W. M. Lansford, *Bulletin No. 289*, Eng. Experiment Station, Univ. of Illinois, Urbana, 1936.

[21] "The Use of Pipe Bends as Flow Meters," by Herbert Addison, ***Engineering*** (London), March 4, 1938, pp. 227–229.

The effect thus shown of the curvature on the pressure difference between the inside and outside curves of a bend should apply equally well to the superelevation of the water surface around a bend in an open channel. From the data presented by Messrs. Yarnell and Woodward[17] on the flow around 180° open and closed rectangular channels, the writer has computed the coefficient K for two different open channel bends. The computations were made from plotted results given for conditions 45° around a 10-in. and a 5-in. wide channel. These data are plotted in Fig. 18, and the agreement with the pipe data is seen to be fair. Finally, the writer has estimated a point from data in Fig. 2(*a*) by means of considerable interpolation. From this figure at the start of the bend (Section 8) Δh is 0.25 in. and V is 0.898 ft per sec, and at 90° around the bend (Section 12) Δh is 0.13 in. and V is 0.832 ft per sec. Assuming the average of these values to be those which apply at a station 45° around the bend, a value of K equal to 1.36 is obtained. For this bend $\frac{r_c}{b}$ is 1.16 and K should be 1.7. In view of the assumptions made this is probably a fair check.

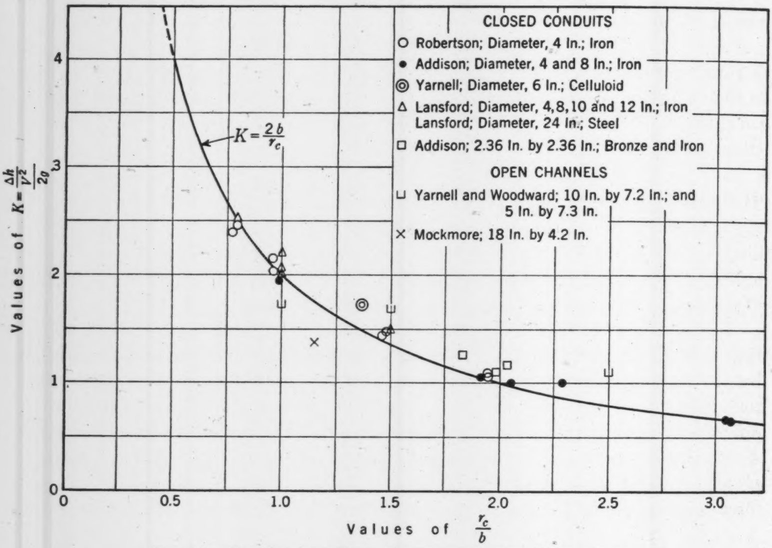

FIG. 18.—VARIATION IN BEND COEFFICIENT WITH CURVATURE

As to the other factors which affect the flow conditions around bends in open and closed channels, the writer has no data of his own to quote. However, he would like to mention the observations of others which may be pertinent to the discussion in connection with the effect of shape of the channel on flow conditions. Mr. Yarnell[18] notes that "the strength of the secondary currents in bends is greater in wide channels than narrow channels." In an excellent discussion[22] of the flow around curved channels and the occurrence of secondary currents, reference is made to some observations of A. Betz[23] on the flow in rectangular channels of different shapes. Fig. 19 indicates the nature of the flow observed in a square and in a narrow rectangular channel showing the regions in which an accumulation of retarded fluid tends to occur. In each case the plan view depicts conditions in the middle of the section and the sectional view conditions at the end of the bend. The explanation for the conditions in the square section are rather simple. As many observers have noted, because of the secondary motion the faster moving fluid in the central part is moving outward, pushing the fluid in the boundary layer at the outer wall to the top and bottom of the channel and thence back toward the inner wall of the bend where it accumulates.

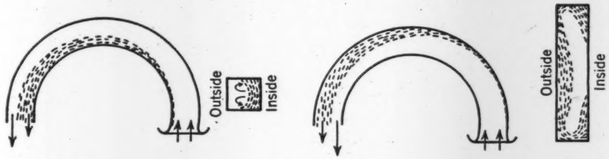

Fig. 19.—Flow Conditions in Square and Deep Rectangular Sectioned Bends

In a narrow, deep curved channel almost the reverse seems to occur as shown in the right side of Fig. 19. Here the secondary currents are confined to the top and bottom parts of the section where they tend to act just as in the square channel. The middle part of the section is too far from the top and bottom for the secondary currents to affect it greatly. The effect of the centrifugal forces on the fluid elements in this region tends to accentuate the retarded layer at the wall.[22] Although this type of action probably rarely occurs in open channels as they are more generally wide and shallow, the explanation given tends to show why (as Mr. Yarnell noted) the secondary currents are stronger in wide channels. Reference should also be made to the observations of V. M. Hegly[24,25] on the flow around a bend in a model canal of compound trapezoidal section. This canal consisted of a deep section and an adjacent shallow section of about one third the depth and about the same width. The velocity distributions are shown to be considerably different when the deep, instead of the shallow, region is against the concave bank.

Joe W. Johnson,[26] Assoc. M. Am. Soc. C. E., and M. A. Selim,[27] Jun. Am. Soc. C. E.—A mathematical analysis of the problem of flow around a bend has been presented in this paper. Some rather extensive and elaborate experimental measurements also are given. The velocity distribution included in the experimental data is sufficiently complete to permit the determination of the velocity-head correction factor α and the momentum factor β,[28] although these terms apparently have not been computed by the author.

From the velocity distributions given in Fig. 2(*a*), values of α and β have been computed and are summarized in Table 3(*a*). These data show the variation of α and β with the location of the various sections. Although not conclusive, the values of the coefficients appear to be highest at the entrance end of the bends and to be least at the exit end.

TABLE 3.—VALUES OF α AND β

Item	(*a*) VARIOUS CROSS SECTIONS						(*b*) SECTION 12		
	Station 8	Station 12	Station 16	Station 20	Station 24	Station 28	Fig. 2(*b*)	Fig. 2(*a*)	Fig. 16
Stage			0.406				0.030	0.406	0.496
Q			0.449 (see Fig. 2(*a*))				....	0.449	0.449
α	1.12	1.13	1.05	1.62	1.37	1.15	1.46	1.13	1.31
β	1.05	1.11	1.02	1.25	1.14	1.04	1.16	1.11	1.14

Another item of interest that could be obtained from the various velocity distributions is a comparison between the values of α and β for a particular section at various stages and discharges. Data from the velocity distributions shown in Figs. 2(*a*), 2(*b*), and 16 for Section 12 are summarized in Table 3(*b*). Unfortunately, the data for only three stages are not enough to warrant any conclusions.

Values of the α and β coefficients for all the velocity distributions observed by the author might show an interesting trend of the data.

TABLE 4.—VALUES OF α FOR A STRAIGHT FLUME

Slope	DEPTH OF FLOW, IN FEET					
	0.8	0.6	0.4	0.3	0.2	0.1
0.0002	1.037	1.068	1.060	....	1.068	....
0.00045	....	1.033	....	....	....	....
0.0005	....	....	1.040	....	1.052	1.045
0.00010	....	....	1.048	1.056	1.063	1.048
0.00015	....	....	1.054	1.098	1.061	1.089
0.00020	....	....	....	1.057	1.071	1.072
0.00040	....	....	....	....	1.057	1.063

Of interest in this latter respect are the values of α observed in a straight flume at the U. S. Waterways Experiment Station.[29] Observation was by pitot tube on the velocity distribution at a section near the center of a flume 48 ft long and 2.31 ft wide, with various depths and slopes. In all observations the water-surface slope was parallel to the bed slope. The values of α for various runs are summarized in Table 4.

Examination of Table 4 shows that, for a particular slope, α tends to increase slightly with decreasing depth. Actually, the range in variation is so slight that for practical purposes the average of the values for all depths and slopes represents a reasonable value of α for a straight flume. Thus, in a reach of a channel with no bends or obstructions the values of α, for most practical purposes, can be assumed equal to 1.

[29] "The Effect of Geometric and Slope Distortion on the Distribution of Energy and Tractive Force in Stream Cross-Sections," *Technical Memorandum No. 32–2*, U. S. Waterways Experiment Station, Vicksburg, Miss., 1936.

I. Nelidov,[30] M. Am. Soc. C. E.—So far as it is known to the writer, there has been no clear exposition of the mechanics of flow in curved channels. Professor Mockmore's accomplishment therefore is that he produced an analysis of the components of the velocities on three orthogonal planes within the body of the current.

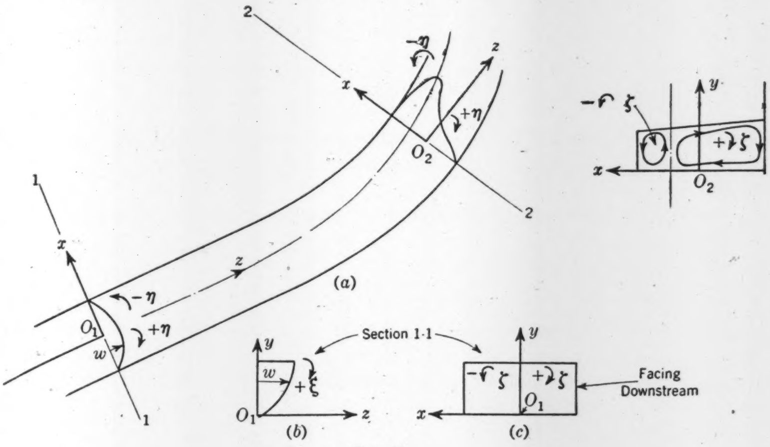

Fig. 20

The writer wishes to illustrate this problem from the standpoint of mechanical analogy to gyroscopic motion. From the theory of gyroscopic[31] motion, if a body is acted on by two orthogonal couples, there will exist, as a result of this action, a third couple orthogonal to the first two couples. Consider a straight part of a channel as shown in Fig. 20(*a*), Section 1–1. The approximate velocity distribution in plan and vertical cross section is known and shown in Figs. 20(*b*) and 20(*c*). This distribution of velocities results in the couples η and ζ. Since these couples have a negative and a positive sign, the water will flow so that, in a straight reach of channel, there will be two spirals, one clockwise and the other counterclockwise.

It may be noted here that M. Möller[32] quotes experiments in the Ruhr River which indicated the reverse direction of spirals from the one in Fig. 20(*c*). However, he maintains that two spirals will exist in a straight reach of channel.

In the curved reach of channel, the relations will be as indicated in Fig. 20(*d*), which is in general agreement with Fig. 5(*b*). If there are reversals in distribution of the velocity *w* either in plan or in a vertical section, there will be, as a result of this condition, some additional couples which, if of opposite sign, may create "dead" water. Therefore, before the direction of spiral rotation is established, a rather complete picture of the distribution of velocity w should be obtained. Considering a reversal of velocities w near the point b in the flow indicated in Section 2–2 in Fig. 20 near the surface (as shown in Fig. 5(c)) and no reversal at the bottom, the rotations as viewed facing downstream will be as shown in Figs. 21(a) and 21(b).

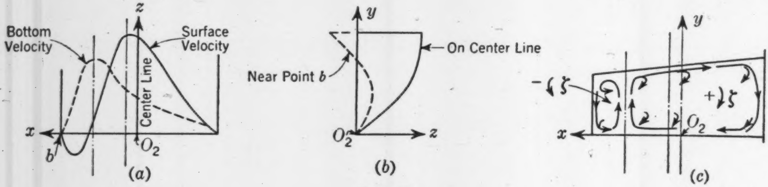

FIG. 21

Professor Mockmore has presented a very clear picture of mechanics of spiral flow.

S. M. WOODWARD,[33] HON. M. AM. SOC. C. E., J. W. HOWE,[34] M. AM. SOC. C. E., AND C. J. POSEY,[35] ASSOC. M. AM. SOC. C. E.—The mechanism of flow around bends in open channels is extremely complicated, and the resultant difficulties of experimentation and observation have kept the number of published investigations small in spite of the pressing practical need for information. This paper contains a lucid description of the spiral motion and several other interesting phenomena, as observed in an experimental channel of adequate dimensions. Use of a simple rectangular channel permits comparison with the results of mathematical analyses based on different assumptions for the distribution of three components of velocity throughout the cross section.

According to the author, the fundamentals of flow around bends in open channels are best studied in the laboratory, rather than in natural streams, because of the irregularity and instability of the stream bed. That the first of these difficulties is not insurmountable has been shown by F. L. Blue, Jr., J. K. Herbert, and R. L. Lancefield,[36] who made a detailed study of a full-sized river bend, and who observed several of the interesting phenomena discovered by the author in his laboratory investigation. Their report probably had much to do with convincing the skeptics referred to by the author.[8]

The most important advantages of the laboratory approach come from the comparative ease with which the main variables can be changed. Thus, otherwise identical runs can be made with different depth-width ratios, with different central angles, and with different ratios of radius of bend to width of channel. Although such a testing program would be lengthy and expensive even in the laboratory, it might yield answers to some of the important unsolved problems in this field.

[35] Res. Engr., Iowa Inst. of Hydraulic Research; Associate Prof., Hydraulics and Structural Eng., State Univ. of Iowa, Iowa City, Iowa.

[36] "Flow Around a River Bend Investigated," by F. L. Blue, Jr., J. K. Herbert, and R. L. Lancefield, *Civil Engineering*, May, 1934, p. 258.

The author's data show that in the bend tested the spiral was strong enough for bottom velocities to carry particles across the center line of the channel at an angle of nearly 45°. How does the "strength" of the spiral vary around the curve? Does it persist in the tangent downstream? How does its strength vary with variation in the dimensions of the bend and of the cross section? What is a satisfactory measure of the strength of the spiral motion?

The author's mathematical analyses both apparently assume that the spiral flow comes suddenly into existence at the point of tangency and remains constant around the bend. Replacement of this assumption with a more reasonable one would add considerably to the complications of the mathematical treatment, and yet would not permit a complete solution to be approached much more closely, for other factors, such as the vertical velocity distribution, still remain to be brought into agreement with observations.

Should the velocity distribution at the point of tangency be assumed to be the normal velocity distribution of the stream in a long, straight portion of its channel? Consideration of the water-surface profile through the beginning of the curve indicates that it is not normal—a deduction[37] made some years ago which is verified by the author's tests.

A question of great practical importance is that of the energy loss due to bends. A. A. Humphreys, Hon. M. Am. Soc. C. E., and Henry L. Abbot give the following formula, based on measurements on the lower Mississippi River:[38]

$$h = \frac{V^2 \sin^2 a}{134} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

in which h is the loss of head in feet, V is the velocity in feet per second, and a is a complicated variable, with only slight claim to rationality, introduced by L. G. Dubuat. It depends upon the radius, central angle, and width of the stream. Its computation is explained in detail by J. F. D'Aubuisson.[39]

An experimental study of a bend of the Iowa River, made in 1913–1914 by B. C. Boer and R. H. Urick, at Iowa University, Iowa City, showed that

$$\text{Loss of head} = \frac{0.0256\, V^2 \times \text{width of stream}}{\text{Geographic radius of curvature}} \quad \ldots\ldots\ldots (34)$$

On the basis of tests of the Tiger Creek flume, F. C. Scobey, M. Am. Soc. C. E., suggests that the value of Kutter's n be increased 0.001 for each 20° of curvature in 100 ft of flume.[40]

C. H. Yen found the head loss in a small 90° bend, rectangular in cross section and having an 11-in. width and 5-ft radius, to be $0.38 \frac{V^2}{2g}$.[41] His measurements of secondary currents indicated that the velocity of the spiral flow was much higher at the bottom of the cross section than elsewhere. Modifications of the geometric proportions of the cross section resulted in large changes in the head loss.

[41] "Effects of Channel Shape on Losses in a Canal Bend," by C. H. Yen and J. W. Howe, *Civil Engineering*, January, 1942, p. 28.

Many features of flow around bends in open channels remain to be understood. Both laboratory investigations and measurements on natural streams will be necessary before the needed fundamental relationships have been formulated and evaluated.

C. A. Mockmore,[42] M. Am. Soc. C. E.—Very properly, Professor Robertson records that well-known textbooks on hydraulics present data and make statements inferring that the filament of maximum velocity is always at the outside of the bend and that, in fact, "the filament of maximum velocity is initially, and, for most of the way around the bend, near the inside of the bend." The maximum velocity filament is at the inside of the bend initially, but is not there near the end of the bend, either in an open or a closed channel. In addition, Professor Robertson presents the results of some very fine experiments which he conducted at the University of Illinois in Urbana with closed pipe bends. Fig. 18 is especially interesting and valuable.

An attempt was made by the writer to evaluate α and β as presented by Messrs. Johnson and Selim. The reason for leaving this study out of the paper is given in their comment—"the data for only three stages are not enough to warrant any conclusions."

Mr. Nelidov applies the theory of gyroscopic motion to flow of a fluid around a bend. The theory works well with solid bodies, but it is difficult to form a clear picture of its application to a stream of water flowing around a bend where there are myriads of exceedingly small particles, molecular in size and not rigidly affixed to one another.

Several interesting questions on the "strength" of the spiral in an open channel are formulated by Messrs. Woodward, Howe, and Posey. It is a delight to contemplate the questions which these discussers would have asked had they been present when the apparatus shown in Fig. 1 was in operation. All the answers must await further researches.

There seems to be a slight misconception of the assumptions for the mathematical analyses. The writer does not assume "that the spiral flow comes suddenly into existence at the point of tangency and remains constant around the bend," but that a particular flow condition exists at a cross section of the bend of the stream, such as that in Fig. 7. Then the curves in Fig. 9 give a graphical representation of the paths various particles of water would take if they were permitted to continue that behavior in a tangent to the bend of the channel. At any other downstream section an entirely new set of flow conditions may obtain.

The writer has read the article by Messrs. Blue, Herbert, and Lancefield,[36] describing a detailed study of a full-sized river bend, and appreciates not only the value of the work but also the hard labor and the occasional hazards incident to collecting such data, since on three different occasions he was spilled out of a boat into a mountain stream (once at flood stage) while attempting to collect river flow data. The writer firmly believes that the fundamentals of stream flow can best be studied in the laboratory, and second best in the field.

EFFECT OF TURBULENCE ON SEDIMENTATION

By William E. Dobbins,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. A. M. Gaudin, John S. McNown, H. A. Einstein, Thomas R. Camp, Garbis H. Keulegan, C. W. Thornthwaite, A. A. Kalinske, E. R. Van Driest, R. Schuhmann, Jr., H. B. Southwood, L. Standish Hall, and William E. Dobbins.

Synopsis

The basic theory of turbulent flow has been applied successfully to explain the observed vertical distribution of suspended matter in streams in which the suspended load is in equilibrium with the bed material. This paper presents the results of studies made in an effort to extend the theory to explain the concentration changes in a stream or settling basin under nonequilibrium conditions. The general differential equation expressing the concentration changes during turbulent sedimentation in an infinitely wide stream is derived, and the complete solution for a certain simplified case is presented. Evidence of the validity of this solution is provided by the results of experiments which are described herein.

Introduction

An attempt to set up a mathematical theory of sedimentation should take into account both the character of the sediment and the character of the fluid motion.

The sediment characteristics to be considered are not only the settling velocities of the individual particles but also the question of whether or not they retain their individualities as they settle. When two particles of a nonflocculent material come together the only effect is the momentary mutual interference; if two particles of a flocculent material come together they may lose their individual identities and become one. Thus, in a suspension of nonflocculent material, the sediment characteristics are constant, whereas in a suspension of flocculent material they are continuously changing.

The characteristics of the fluid motion under consideration are not only the motion of the fluid as a whole but also the momentary fluctuations from the average motion at every point in the fluid mass. To take into account the mo-

---

Note.—Published in February, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Engr., Industrial Div., Stone and Webster Eng. Corp., Boston, Mass.

tion of the fluid as a whole, the boundaries of the flow, the average point velocities, and the variations of these with time should be studied. Besides these factors, all secondary motions, such as convection or displacement currents and the fluctuations which are characteristic of turbulent flow, must be considered if the fluid motion is to be completely defined.

A complication arises through the fact that there is not complete independence between the sediment and the fluid flow characteristics. In the case of a flocculent material, the rate at which and the extent to which coagulation takes place are influenced by the nature of the flow. Any mixing of the fluid will increase the chances of contact between the individual particles, and hence the speed of coagulation. On the other hand, the shear stresses set up in the particles by the velocity gradients tend to limit the size to which the particles can grow.

In a horizontal flow tank, any upward flow caused by a secondary motion at some point must be compensated by a downward flow at the same rate at some other point. This is obviously necessary if the fluid mass is to remain continuous. In a suspension of particles which are settling out, the suspended matter tends to become more concentrated toward the bottom than above, although the suspension may be clearing throughout the entire depth. An upward flow, then, carries fluid from a region in which the concentration of suspended matter is high into one in which it is relatively low. Likewise, a downward current carries fluid with a low concentration into a region where the concentration is high. Thus, one effect of the secondary motion is to create an upward transport which tends to retard the rate at which the suspension clears. On the other hand, the secondary motion might increase the rate of coagulation and there also tend to increase the rate of clearance. It is clear, then, that whether or not a suspension of flocculent material will settle more rapidly in a turbulent fluid than in a quiescent fluid will depend upon the relative magnitudes of the effects of the turbulence in increasing the rate of coagulation and in transporting the material upward. In a suspension of discrete particles, the upward transport is the only effect of turbulence and hence the rate of clearance is retarded.

The complexities involved in the analysis of the secondary motions themselves combined with those involved in the analysis of the coagulation phenomenon make the analysis of the sedimentation problem very difficult. However, an understanding of the separate effects of secondary motions and of coagulation on sedimentation would be helpful in understanding the entire phenomenon.

One of the earliest and most widely known attempts to set up a mathematical theory for settling in a sedimentation basin was made by the late Allen Hazen, M. Am. Soc. C. E. (1).[2] He distinguished between quiescent and "turbulent" flow and restricted his analysis to suspensions of discrete particles having a single settling velocity. The principal contribution which he made was to demonstrate that the extent of the removal of discrete particles in a quiescent basin is independent of the depth of the basin. His analysis of sedimentation in turbulent basins is incorrect because it is based on incorrect assumptions.

---

[2] **Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix 1).**

The case of sedimentation of discrete particles of varying settling velocities in a quiescent basin has been presented by T. R. Camp, M. Am. Soc. C. E. (2).

The study described herein concerns the case of the sedimentation of discrete particles of uniform size in a stream in which turbulence is fully developed. By "fully developed turbulence" is meant a condition such that, although the velocity at every point is in a continuous state of flux, there is a statistical average velocity that remains constant. Modern developments in fluid mechanics have led to an understanding of the phenomenon of turbulence which has enabled a rational attack to be made on the sedimentation problem.

BASIC THEORY OF SEDIMENT SUSPENSION BY TURBULENCE

Notation.—The letter symbols introduced in this paper are defined where they first appear and are assembled for convenience of reference in Appendix 2.

The Principle of Turbulent Transport.—In the modern theory of turbulence it has been shown that the intensity of shear τ at a point in a moving fluid is

$$\tau = \rho |\bar{v}'_y| \, l \, \frac{\partial \bar{v}_x}{\partial y} \dots\dots\dots\dots\dots\dots\dots\dots (1)$$

in which ρ is the fluid density; l is the Prandtl (3) "mixing length"; $|\bar{v}'_y|$ is the absolute magnitude without regard to sign of the temporal mean value of the fluctuation velocity in the y-direction; and $\frac{\partial \bar{v}_x}{\partial y}$ is the temporal mean velocity gradient. Eq. 1 expresses the fact that the rate of transport of momentum per unit volume across any stream line is proportional to the gradient of the momentum per unit volume in the direction of the transfer. Theodor von Kármán, M. Am. Soc. C. E. (4), showed that the rate of transport of any local characteristic of the fluid, such as its heat content, salinity, or silt content, can be expressed by an equation similar to Eq. 1. If c represents the magnitude per unit volume of such a characteristic and $|\bar{v}'_s|$ is the mean numerical value of the velocity fluctuations of the fluid in any direction s, the rate of transport of the local characteristic in the direction of s will be given by

$$-\beta |\bar{v}'_s| \, l \, \frac{\partial c}{\partial s} = -\epsilon \frac{\partial c}{\partial s} \dots\dots\dots\dots\dots\dots\dots (2)$$

the minus sign indicating that the net transport is in the direction of decreasing c, and β being a factor whose value depends upon the characteristic being considered. The quantity ϵ is called the exchange or mixing coefficient. If c represents the momentum per unit volume and s is taken in the direction normal to the flow, the value of β is unity.

If c represents the magnitude or intensity of some inherent characteristic of the fluid, such as its heat content or color, it seems likely that the value of β would also be unity, since the characteristic would be transported by the transport of the fluid itself. This has been confirmed by A. A. Kalinske, Assoc. M. Am. Soc. C. E., and J. M. Robertson, Jun. Am. Soc. C. E. (5), in studying the diffusion of droplets of dye which had the same density as the water in which the diffusion took place.

In case c is the concentration of sediment in suspension, it is to be expected that the value of β might differ somewhat from unity, because the presence of the sediment increases the density of the fluid as a whole and thus alters the pattern of the turbulence, and also because the mixing of the suspended particles might not be the same as for the fluid masses. In studying suspensions of sand grains in water, Hunter Rouse, M. Am. Soc. C. E. (6), found that the value of β was the same for all suspensions in which the grain sizes were less than $\frac{1}{16}$ mm in diameter but that it changed for suspensions of larger grains. He was dealing with concentrations up to about 3% by weight. Since he found no systematic deviations in the value of β for material of any one size when the concentrations were varied, he attributed the variations with grain size to the fact that the mixing of the larger grains was not the same as that of the fluid itself. He had no means of determining the actual values of β, but simply the degrees of variation. Experiments by V. A. Vanoni, Assoc. M. Am. Soc. C. E. (7), indicated a value of β close to unity when dealing with relatively low concentrations of small grains. It is probable that the value of β can be taken as unity in most practical cases.

The Theory of Sediment Suspension.—In a turbulent stream the eddies dig into the bed and carry material into suspension. This action is opposed by the settling of the particles due to their own weight. If steady conditions prevail, there will be an equilibrium between the rate at which sediment is raised from the bed by the turbulence and the rate at which it settles on to the bed again. At every elevation above the bed, a similar equilibrium will result between the rate of upward transport due to the turbulence and the rate of fall due to the weight of the particles. Thus the concentration will remain constant at every elevation, although the particles of which the suspension is composed will be changing continuously.

If the concentration at any elevation, y, be denoted by c, and the settling velocity of the particles by w, the rate at which the material settles through a unit area at the elevation y is $w\,c$. If the state of equilibrium exists, this rate will be balanced by the rate of turbulent transport upward, and

$$w\,c = -\,\epsilon\,\frac{\partial c}{\partial y} \qquad (3)$$

This equation was first used by W. Schmidt (8) in studying the distribution of dust particles in air and was applied to the problem of silt suspension by Morrough P. O'Brien, M. Am. Soc. C. E. (9). Integration of Eq. 3 yields an expression for the concentration, c, in terms of the concentration, c_a, at some arbitrary elevation, a:

$$\log_e \frac{c}{c_a} = -\,w \int_a^y \frac{dy}{\epsilon} \qquad (4)$$

To evaluate the integral in Eq. 4 it is necessary to express ϵ as a function of y.

The general validity of Eq. 4 was established by Professor Rouse (6) in experiments in which a uniform intensity of turbulence was imposed on a suspension of sand in water by means of an agitating mechanism. Under such conditions, ϵ is independent of y and Eq. 4 becomes

$$c = c_a \, e^{-w\epsilon^{-1}(y-a)} \quad \text{.......................} \quad (5a)$$

in which e is the base of Naperian logarithms. If it is assumed that ϵ is constant down to the mean level of the top of the bed material, a can be assumed zero and Eq. 4 reduces to

$$c = A \, e^{-wy\epsilon^{-1}} \quad \text{.........................} \quad (5b)$$

in which A is the concentration at $y = 0$. In such a distribution, the total sediment, W, held in suspension per unit area between any two elevations, y_1 and y_2, is given by the expression

$$W = \int_{y_1}^{y_2} c \, dy = \frac{c_1 \, \epsilon}{w} \left(1 - \frac{c_2}{c_1} \right) \quad \text{..................} \quad (6)$$

If the values of the concentrations at any two elevations, y_1 and y_2, are known, the value of $\frac{w}{\epsilon}$ can be computed from the equation,

$$\frac{w}{\epsilon} = \frac{1}{y_2 - y_1} \log_e \frac{c_2}{c_1} \quad \text{.......................} \quad (7)$$

In an actual stream, ϵ varies with the distance from the bed and also from point to point across the section. If the flow is unsteady and nonuniform it will also vary from section to section and from time to time. If the discussion is limited to the case of steady uniform flow in the central region of a very wide stream, ϵ will be a function of y alone. In such a case, the value of the shear, τ, at any distance y from the bottom is given by the expression,

$$\tau = \tau_0 \left(1 - \frac{y}{h} \right) \quad \text{........................} \quad (8)$$

in which h is the total depth and τ_0 is the bottom shear. If this is combined with Eq. 1—

$$\epsilon = \beta \, \frac{\tau_0}{\rho} \frac{1 - \dfrac{y}{h}}{\dfrac{dV}{dy}} \quad \text{........................} \quad (9)$$

in which $\bar{v}_x$ has been replaced by V. It has been shown by G. H. Keulegan (10) and also by Mr. Vanoni (11) that the von Kármán universal logarithmic velocity law for pipes can be applied to the case of uniform two-dimensional open-channel flow, yielding the expression

$$V = \overline{V} + \frac{1}{\kappa} \sqrt{\frac{\tau_0}{\rho}} \left(1 + \log_e \frac{y}{h} \right) \quad \text{...............} \quad (10a)$$

from which

$$\frac{dV}{dy} = \frac{1}{\kappa} \sqrt{\frac{\tau_0}{\rho}} \frac{1}{y} \quad \text{.......................} \quad (10b)$$

Using this value for the velocity gradient, Eq. 9 becomes

$$\epsilon = \beta \kappa \sqrt{\frac{\tau_0}{\rho}} \left(1 - \frac{y}{h}\right) y = \beta \kappa \overline{V} \sqrt{\frac{f}{8}} \left(1 - \frac{y}{h}\right) y$$

$$= \beta \kappa \sqrt{g h S} \left(1 - \frac{y}{h}\right) y \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

In these expressions, κ is the von Kármán universal constant having a value approximately equal to 0.40; $\overline{V}$ is the mean velocity of flow; f is the Darcy friction factor for the bed; g is the acceleration of gravity; and S is the slope of the energy gradient.

Eq. 11 indicates a value of ϵ which is a maximum at $y = \frac{h}{2}$ and which approaches zero as y approaches both zero and h. This general trend has been verified by Messrs. Kalinske and Robertson (5), who made measurements of ϵ by observing the spread of droplets of dye which were injected into a rectangular channel at various points in the cross section. If the value of ϵ, as given by Eq. 11, is used in Eq. 4, the expression for the distribution of sediment becomes

$$\frac{c}{c_a} = \left(\frac{\frac{h}{y} - 1}{\frac{h}{a} - 1}\right)^z \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

in which

$$z = \frac{w}{\kappa \beta \sqrt{\frac{\tau_0}{\rho}}} = \frac{w}{\kappa \beta \overline{V} \sqrt{\frac{f}{8}}} \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

Experiments by Mr. Vanoni (7) have indicated close agreement between the actual distribution in a turbulent channel and the distribution as expressed by Eqs. 12 and 13 when the values of κ and β were taken as 0.40 and unity, respectively. He found that the agreement was close throughout the major range of the depth.

It would seem that the value of ϵ cannot be absolutely zero at either the bed or the surface because a value of zero at the surface would indicate that the surface is absolutely smooth, and a value of zero at the bed would indicate no pickup. The experimental measurements of Messrs. Kalinske and Vanoni indicate, however, that ϵ follows the functional trend of Eq. 11 as close to the bed and the surface as measurements are practically possible.

The foregoing expressions refer the value of c at any elevation, y, to its value at some arbitrary elevation, a. Thus, these expressions determine the shape of the concentration curves but give no indication of the absolute magnitudes. They also apply only to the case of sediments made up of particles having a single settling velocity.

The absolute magnitudes of the concentrations should depend upon the bottom conditions. In experiments described subsequently in this paper a uniform mixing was imposed upon a suspension of particles of a fairly uniform size in a cylindrical container. The resulting equilibrium concentration for a given depth and a given degree of mixing depended only upon the distance of the mixing apparatus from the bottom, provided that the bottom was completely covered with the sediment when the equilibrium condition was reached.

Although many variables determine the flow pattern in a stream, a given combination of these variables will result in a definite flow condition. Hence, it seems logical to assume that there will be a definite rate of pickup of a given type of sediment. At the time of this writing the analysis of the problem has not progressed to the point where the rate of pickup can be expressed as a function of the variables involved.

DEVELOPMENT OF THE THEORY OF SEDIMENTATION FOR TURBULENT CONDITIONS

Statement of the Problem.—The equilibrium condition described in the previous chapter is a condition which is approached but is never fully reached. The silt content of a natural stream at some section might be more or less than the ultimate transport capacity because of a sudden change in the cross section immediately upstream. If steady uniform flow prevails downstream, sediment will be deposited or picked up as the new equilibrium condition is approached. In a settling tank the content of suspended matter at the inlet end is much greater than the carrying capacity, and so the material settles out. It is with the changes in concentration from section to section that this study is mainly concerned. The discussion is confined to the two-dimensional case corresponding to the conditions of steady uniform flow in the central region of a wide channel.

Derivation of the Differential Equation for Sedimentation in a Turbulent Stream.—With reference to Fig. 1, the x-axis is taken at the bottom of the channel in the direction of the flow. For the sake of generality, the concentration is assumed to increase with both x and y and the velocity with y. Consider the point m (x,y) and the element mm′nn′ having the dimensions dx and dy in the x,y-plane and unity in the normal direction, and let c be the concentration of suspended matter at any time t at the point m.

If the amount of suspended matter carried out of the element across the face nn′ by turbulence and settling and across the face m′n′ by turbulence and the flowing stream is subtracted from the weight carried into the element across the opposite faces, it may be shown that

$$\frac{dW}{dx\,dy\,dt} = \epsilon_y \frac{\partial^2 c}{\partial y^2} + \frac{\partial \epsilon_y}{\partial y}\left(\frac{\partial c}{\partial y} + \frac{\partial^2 c}{\partial y^2}dy + \frac{\partial^2 c}{\partial x\,\partial y}\frac{dx}{2}\right) + \epsilon_x \frac{\partial^2 c}{\partial x^2} + \frac{\partial \epsilon_x}{\partial y}\frac{\partial^2 c}{\partial x^2}\frac{dy}{2} + w\frac{\partial c}{\partial y} - \left(V + \frac{\partial V}{\partial y}\frac{dy}{2}\right)\frac{\partial c}{\partial x} \;\ldots\ldots\; (14a)$$

in which dW is the net increased amount of suspended matter in the element in time dt.

For the steady state, the concentration at a fixed point remains unchanged with time. Therefore, $\dfrac{dW}{dx\,dy\,dt} = 0$. The other terms which contain the factors dy and dx also become zero as the element $dx\,dy$ approaches a point. Then the final equation becomes

$$V\frac{\partial c}{\partial x} = \epsilon_y\frac{\partial^2 c}{\partial y^2} + \left(w + \frac{\partial \epsilon_y}{\partial y}\right)\frac{\partial c}{\partial y} + \epsilon_x\frac{\partial^2 c}{\partial x^2} \qquad (14b)$$

FIG. 1.—CONCENTRATION GRADIENTS IN THE CENTRAL REGION OF A WIDE CHANNEL

Eq. 14b is the general differential equation for the concentration changes in the two-dimensional case. An equation similar to 14b, but which does not take into account the term $\frac{\partial \epsilon_y}{\partial y}\frac{\partial c}{\partial y}$, has been presented by Professor Kalinske (14). Before a solution for Eq. 14b can be found, the factors V, ϵ_y, and ϵ_x must be expressed as functions of y. Eq. 10a expresses the necessary relationship for V and Eq. 11 gives the proper function for ϵ_y. It has already been stated that the value of ϵ_x is probably equal to or at least proportional to ϵ_y.

Simplifications of the General Differential Equation.—No solution has been obtained for the general two-dimensional case as expressed in Eq. 14b. However, the equation can be greatly simplified by making certain assumptions. If the velocity distribution were assumed to follow a parabolic law instead of the logarithmic law expressed in Eq. 10*a*, the velocity equation could be written (see Fig. 2).

$$V = V_s - k\,(h - y)^2 \qquad \text{(15a)}$$

in which V_s is the velocity at the surface and k is the constant of the parabola. Then

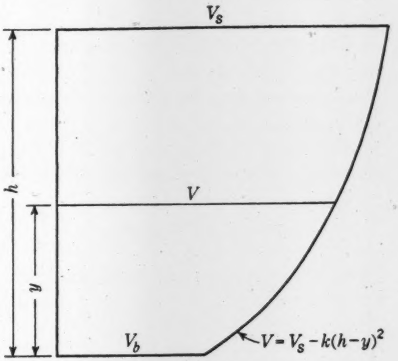

FIG. 2.—PARABOLIC VELOCITY DISTRIBUTION

$$\frac{dV}{dy} = 2\,k\,h\left(1 - \frac{y}{h}\right) \qquad \text{(15b)}$$

From Eq. 9, assuming β to be unity,

$$\epsilon_y = \frac{\tau_0}{\rho}\,\frac{1 - \dfrac{y}{h}}{\dfrac{dV}{dy}} \qquad \text{(16a)}$$

Combining Eqs. 15*b* and 16*a* gives

$$\epsilon_y = \frac{\tau_0}{2\,k\,h\,\rho} \qquad \text{(16b)}$$

which is a constant for any particular flow condition. If it is further assumed that $\epsilon_x \dfrac{\partial^2 c}{\partial x^2} = 0$ (that is, there is no diffusion of the suspended matter in the x-direction), the differential equation reduces to

$$[V_s - k\,(h - y)^2]\,\frac{\partial c}{\partial x} = \epsilon_y \frac{\partial^2 c}{\partial y^2} + w\,\frac{\partial c}{\partial y} \qquad \text{(17a)}$$

A further simplification is obtained if it is assumed that V is constant throughout the depth, $\epsilon_x \dfrac{\partial^2 c}{\partial x^2}$ is zero, and ϵ_y is constant. In this case, Eq. 17*a* becomes

$$V\,\frac{\partial c}{\partial x} = \epsilon\,\frac{\partial^2 c}{\partial y^2} + w\,\frac{\partial c}{\partial y} \qquad \text{(17b)}$$

For the case in which the body of the liquid has no motion as a whole but has a uniform turbulence imposed on it throughout, the independent variables become y and t, and the differential equation becomes

$$\frac{dW}{dx\,dy\,dt} = \frac{\partial c}{\partial t} = \epsilon\,\frac{\partial^2 c}{\partial y^2} + w\,\frac{\partial c}{\partial y} \qquad \text{(17c)}$$

Eqs. 17*b* and 17*c* are identical mathematically, because if V is constant, $V\dfrac{\partial c}{\partial x}$ is equivalent to $\dfrac{\partial c}{\partial t}$, in which t is equal to $\dfrac{x}{V}$.

It is to be realized that the simplifying assumptions involved in Eqs. 17 may introduce large errors when applied to the case of a natural stream. The assumption of a parabolic velocity distribution need not introduce large errors in the values of V but it does introduce considerable error in the value ϵ_y. The equation for this case was presented to show that the assumption of a constant value for ϵ_y is equivalent to assuming a parabolic velocity distribution. The assumption that the value of $\epsilon_x \dfrac{\partial^2 c}{\partial x^2}$ equals zero would not introduce a very large error if the concentration gradient in the x-direction were small compared to the gradient in the vertical direction. This would be the case when the concentrations do not differ greatly from the final equilibrium concentrations.

Boundary Conditions.—The solution for any practical case must satisfy not only the differential equation for that case but also the boundary conditions. The latter are four in number, two of which specify the conditions that prevail at the surface and at the bed, and two of which specify the original and the final distributions of the suspended matter. The rate of transport of sediment across any plane, $y = y_1$, is given by the expression

$$\text{Transportation rate} = \epsilon_y \left(\frac{\partial c}{\partial y}\right)_{y_1} + w\, c_{y_1} \qquad (18)$$

There is no transport of material across the surface, in any case, and so the first boundary condition which must be satisfied is

$$\text{(I)} \qquad \left(\frac{\partial c}{\partial y}\right)_h = -\frac{w}{\epsilon_y} c_h$$

Since c_h varies with x or t, the concentration gradient at the surface is not a constant.

The rate at which material is picked up from the bottom by the turbulence is $-\epsilon_y \left(\dfrac{\partial c}{\partial y}\right)_{y=0}$. The minus sign accounts for the fact that the pickup is positive when the concentration gradient is negative. The rate of pickup of a given type of sediment depends only upon the characteristics of the flow and so, for steady uniform flow, the pickup will be constant. At the equilibrium condition the rate of pickup equals the rate of deposit, $w\, c_0$, and so the second boundary condition is

$$\text{(II)} \qquad \epsilon_y \left(\frac{\partial c}{\partial y}\right)_{y=0} = -w\, c_{\substack{y=0\\t=\infty}} = -w\, A$$

The third boundary condition is simply that the concentration at time $t = 0$ is some function of y between the limits of zero and h:

$$\text{(III)} \qquad c = f(y) \quad \text{when} \quad 0 < y < h, \quad \text{and} \quad t = 0$$

The fourth boundary condition is

(IV)............The concentration distribution approaches the equilibrium distribution as t approaches infinity.

For a channel this is expressed by Eq. 12 and for the case of a uniform turbulence throughout the fluid by Eqs. 5.

Solution of the Differential Equation for the One-Dimensional Case.—Eq. 17*c*, and its equivalent Eq. 17*b*, are the only forms of the differential equation which have yielded to an analytical solution. The problem in this case is to find a solution to the differential equation, Eq. 17*c*, in which ϵ and w are constants, that satisfies the boundary conditions as defined by I, II, III, and IV.

A particular solution to the differential equation can be obtained by assuming that the solution is a product of two functions—one a function of y alone and the other a function of t alone. Then

$$c = Y(y) \times T(t) \tag{19}$$

By Eq. 17*c*,

$$\frac{T'}{T} = \frac{\epsilon\, Y'' + w\, Y'}{Y} \tag{20}$$

Since each side of this equation is a function of only one of the independent variables, it can hold only if each member is equal to some constant, say $-\,k^2$. Then

$$T' + k^2\, T = 0 \tag{21a}$$

and

$$Y'' + w\, Y' + k^2\, Y = 0 \tag{21b}$$

The solution for T is found directly as

$$T = C_1\, e^{-k^2 t} \tag{22}$$

in which C_1 is an arbitrary constant. The equation involving Y is a second-order linear differential equation which has the well-known solution

$$Y = e^{-0.5\, w y \epsilon^{-1}}\, (C_2 \cos \alpha\, y + C_3 \sin \alpha\, y) \tag{23}$$

in which C_2 and C_3 are arbitrary constants, the exponent of e is $-\,\frac{w\, y}{2\,\epsilon}$, and

$$\alpha^2 = \frac{k^2}{\epsilon} - \frac{w^2}{4\,\epsilon^2} \tag{24}$$

Then the equation,

$$c = e^{-k^2 t}\, e^{-0.5\, w y \epsilon^{-1}}\, (C_1 \cos \alpha\, y + C_2 \sin \alpha\, y) \tag{25}$$

in which the constants are redefined, satisfies the differential equation.

It can be shown easily that the boundary condition for $t = \infty$ also satisfies Eq. 17*c*, and so

$$c = A\, e^{-w y \epsilon^{-1}} + e^{-k^2 t}\, e^{-0.5\, w y \epsilon^{-1}}\, (C_1 \cos \alpha\, y + C_2 \sin \alpha\, y) \tag{26}$$

satisfies both the differential equation and the $t = \infty$ condition. In Eq. 26, A = the concentration at $y = 0$ and $t = \infty$.

To satisfy the boundary conditions for $y = 0$ and $y = h$ it is necessary to differentiate Eq. 26 with respect to y and to compare the result with conditions I and II. Performing the differentiation, there results:

$$\begin{aligned}\frac{\partial c}{\partial y} &= -\,\frac{w}{\epsilon}\, A\, e^{-w y \epsilon^{-1}} + e^{-k^2 t}\, e^{-0.5\, w y \epsilon^{-1}} \\ &\times \left[\sin \alpha\, y \left(-\, C_1\, \alpha - \frac{w}{2\,\epsilon}\, C_2\right) + \cos \alpha\, y \left(C_2\, \alpha - \frac{w}{2\,\epsilon}\, C_1\right)\right]\end{aligned} \tag{27a}$$

When $y = 0$, this reduces to

$$\frac{\partial c}{\partial y} = -\frac{w}{\epsilon} A + e^{-k^2 t}\left(C_2\,\alpha - \frac{w}{2\,\epsilon} C_1\right) \qquad (27b)$$

By comparing this with the boundary condition for $y = 0$ (Condition II) it is seen that

$$C_2\,\alpha - \frac{w}{2\,\epsilon} C_1 = 0 \qquad (28a)$$

and

$$C_2 = \frac{w}{2\,\epsilon\,\alpha} C_1 \qquad (28b)$$

Comparing Eq. 27*a* with Condition I in which the value of C from Eq. 26 has been inserted, it is seen that

$$-\frac{w}{\epsilon}(C_1 \cos \alpha\, h + C_2 \sin \alpha\, h) = \left(C_2\,\alpha - \frac{w}{2\,\epsilon} C_1\right)\cos \alpha\, h - \left(C_1\,\alpha + \frac{w}{2\,\epsilon} C_2\right)\sin \alpha\, h \qquad (29)$$

from which

$$\tan \alpha\, h = \frac{C_2\,\alpha + \dfrac{w\,C_1}{2\,\epsilon}}{C_1\,\alpha - \dfrac{w\,C_2}{2\,\epsilon}} \qquad (30)$$

By combining Eq. 30 with Eq. 28 and changing it into a more convenient form, the following is obtained:

$$\eta = 2 \cot h\,\alpha = \frac{h\,\alpha}{\dfrac{w\,h}{2\,\epsilon}} - \frac{\dfrac{w\,h}{2\,\epsilon}}{h\,\alpha} \qquad (31)$$

Then, a solution of the differential equation which satisfies all of the boundary conditions except Condition III ($t = 0$) is given by

$$c = A\,e^{-wy\epsilon^{-1}} + e^{-0.5\,wy\epsilon^{-1}}\,e^{-k^2 t}\,C_1\left(\cos \alpha\, y + \frac{w}{2\,\epsilon\,\alpha}\sin \alpha\, y\right) \qquad (32a)$$

in which α is defined by Eq. 31, and k^2 is defined by Eq. 24. Inspection of Eq. 31 will reveal that for any given values of w, h, and ϵ there is an infinite number of real positive roots for α, any one of which could be used in Eq. 32*a*. Then, because of the linear nature of the differential equation, the most general solution is

$$c = A\,e^{-wy\epsilon^{-1}} + e^{-0.5\,wy\epsilon^{-1}} \times \sum_{n=1}^{\infty} e^{-(\alpha^2{}_n\epsilon + 0.25\,w^2\epsilon^{-1})t}\,C_n\left(\cos \alpha_n\, y + \frac{w}{2\,\epsilon\,\alpha_n}\sin \alpha_n\, y\right) \qquad (32b)$$

To satisfy Condition III, C_n must now be chosen so that $c = f(y)$ when $t = 0$ and $0 < y < h$. Taking t as zero and c as $f(y)$ in Eq. 32*b*:

$$f(y) = A\, e^{-wy\epsilon^{-1}} + e^{-0.5\, wy\epsilon^{-1}} \sum_{n=1}^{\infty} C_n \left(\cos \alpha_n y + \frac{w}{2\, \epsilon\, \alpha_n} \sin \alpha_n y \right) \ldots (33a)$$

and

$$[f(y) - A\, e^{-wy\epsilon^{-1}}]\, e^{+0.5\, wy\epsilon^{-1}} = \sum_{n=1}^{\infty} C_n\, Y_n \ldots\ldots\ldots\ldots (33b)$$

in which

$$Y_n = \cos \alpha_n y + \frac{w}{2\, \epsilon\, \alpha_n} \sin \alpha_n y \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

The expression for C_n can be derived in a manner presented by H. S. Carslaw (15). The complete derivation for C_n which is on file in the Engineering Societies Library (see "Acknowledgments") yields the following:

$$C_n = \frac{2\, \alpha^2_n}{\left(\alpha^2_n + \frac{w^2}{4\, \epsilon^2} \right) h + \frac{w}{\epsilon}} \int_0^h [f(y) - A\, e^{-wy\epsilon^{-1}}]\, e^{0.5\, wy\epsilon^{-1}}\, Y_n\, dy \ldots (35)$$

Then the final solution to the problem is

$$c = A\, e^{-wy\epsilon^{-1}} + e^{-0.5\, wy\epsilon^{-1}} \sum_{n=1}^{\infty} e^{-(\alpha^2_n \epsilon + 0.25\, w^2 \epsilon^{-1})\, t}\, C_n\, Y_n \ldots\ldots (36)$$

in which Y_n is defined by Eq. 34, C_n by Eq. 35, and $\alpha_1, \alpha_2, \cdots \alpha_n$ are the successive real positive roots of the transcendental formula (Eq. 31).

The roots of Eq. 31 are found most easily by the graphical method illustrated in Fig. 3. The values of $h\, \alpha$ are plotted as abscissas and values of the expressions on each side of the equation as ordinates. The values of $h\, \alpha$ corresponding to the points of intersection of the curves are the values to be used in Eq. 36. It is to be noted that the curves of $2 \cot h\, \alpha$ corresponding to the successive values of α are the same for all cases, but that the proper intersecting curve to use depends upon the value of the ratio $\frac{w\, h}{2\, \epsilon}$. Since ϵ is a product of a velocity and a length, the ratio $\frac{w\, h}{2\, \epsilon}$ is dimensionless and Fig. 3 is a dimensionless plot.

Solutions of Eq. 36 for Various Cases.—If the distribution of sediment at time $t = 0$ is represented by the equation

$$f(y) = c_0\, e^{-By} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

in which c_0 is the concentration at $y = 0$, $t = 0$, and B is in general not equal to $\frac{w}{\epsilon}$, the expression for C_n becomes

$$C_n = \frac{2\, \alpha^2_n}{\left(\alpha^2_n + \frac{w^2}{4\, \epsilon^2} \right) h + \frac{w}{\epsilon}} \int_0^h (c_0\, e^{-By} - A\, e^{-wy\epsilon^{-1}})\, e^{0.5\, wy\epsilon^{-1}}\, Y_n\, dy \ldots (38)$$

The integral in Eq. 38 may be evaluated so that

$$C_n = \frac{2\,\alpha^2{}_n}{\left(\alpha^2{}_n + \dfrac{w^2}{4\,\epsilon^2}\right) h + \dfrac{w}{\epsilon}}$$

$$\times \left\{ \frac{c_0 \left[B + \left(\dfrac{w}{\epsilon} - B \right) e^{(0.5\,w\,\epsilon^{-1} - B)h}\, H_n \right]}{\left(\dfrac{w}{2\,\epsilon} - B \right)^2 + \alpha^2{}_n} - \frac{A\,\dfrac{w}{\epsilon}}{\alpha^2{}_n + \dfrac{w^2}{4\,\epsilon^2}} \right\} \dots\dots (39a)$$

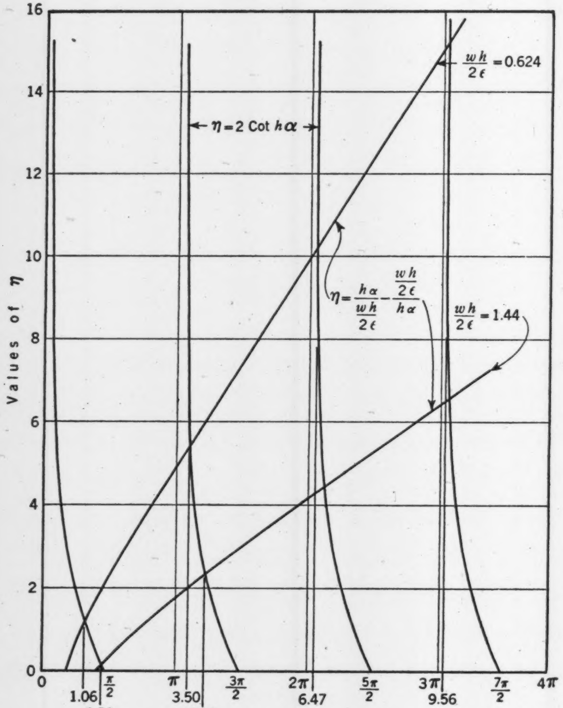

FIG. 3.—GRAPHICAL SOLUTION OF EQ. 31

in which

$$H_n = \cos \alpha_n h + \frac{w}{2\,\epsilon\,\alpha_n} \sin \alpha_n h \dots\dots\dots\dots\dots (39b)$$

With the aid of Eq. 31, it can be shown readily that the value of H_n is ± 1, the plus sign applying for odd values of n and the minus for even values of n.

If the value of B is zero, the concentration at time $t = 0$ is uniform and equal to c_0. The expression for C_n in this case is

$$C_n = \frac{2\,\alpha^2{}_n\,w\,(c_0\,e^{0.5\,wh\epsilon^{-1}}\,H_n - A)}{\left(\alpha^2{}_n\,\epsilon + \frac{w^2}{4\,\epsilon}\right)\left[\left(\alpha^2{}_n + \frac{w^2}{4\,\epsilon^2}\right)h + \frac{w}{\epsilon}\right]} \quad \ldots\ldots\ldots\ldots (40a)$$

If $B = \frac{w}{\epsilon}$, Eq. 39*a* reduces to

$$C_n = \frac{2\,\alpha^2{}_n\,w\,(c_0 - A)}{\left(\alpha^2{}_n\,\epsilon + \frac{w}{4\,\epsilon}\right)\left[\left(\alpha^2{}_n + \frac{w^2}{4\,\epsilon^2}\right)h + \frac{w}{\epsilon}\right]} \quad \ldots\ldots\ldots\ldots (40b)$$

and Eq. 36 becomes

$$c = A\,e^{-wy\epsilon^{-1}} + (c_0 - A)\,e^{-0.5\,wy\epsilon^{-1}}$$

$$\times \sum_{n=1}^{\infty} \frac{2\,\alpha^2{}_n\,w\,e^{-(\alpha^2{}_n\epsilon + 0.25\,w^2\epsilon^{-1})\,t}\,Y_n}{\left(\alpha^2{}_n\,\epsilon + \frac{w^2}{4\,\epsilon}\right)\left[\left(\alpha^2{}_n + \frac{w^2}{4\,\epsilon^2}\right)h + \frac{w}{\epsilon}\right]} \quad \ldots\ldots\ldots\ldots (41)$$

Eq. 41, with c_0 taken as zero, is the solution for the case of scour in which the original concentration is zero for all values of y. With A taken as zero, it is the solution for the case of settling out from the equilibrium concentrations to zero concentration at all depths. It is to be noted that the solution represented by the complete equation is the sum of these two solutions.

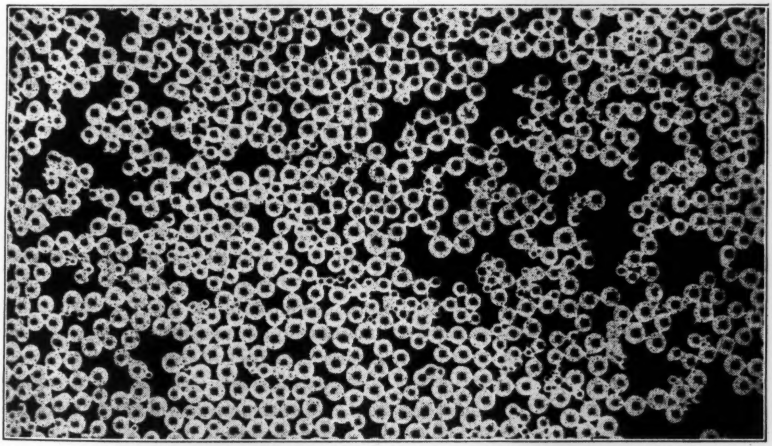

FIG. 4.—ENLARGED VIEW OF MOLDING POWDER PARTICLES

EXPERIMENTAL WORK

Scope and Purpose.—The experimental work was confined to a study of the one-dimensional case and had the primary object of verifying the equations developed in the previous section.

Description of the Suspensions Used in the Experiments.—The material used for the sediment in all of the experiments was the molding powder of a methyl methacrylate resin called "lucite." This material was obtained in the unplasticized and unlubricated state. The powder is made up of transparent spherical particles, most of them ranging in diameter from one tenth of a millimeter to one quarter of a millimeter. An average value of 1.194 g per cu cm was obtained for the density when measured by the pycnometer bottle method and by computation from the results of settling velocity measurements.

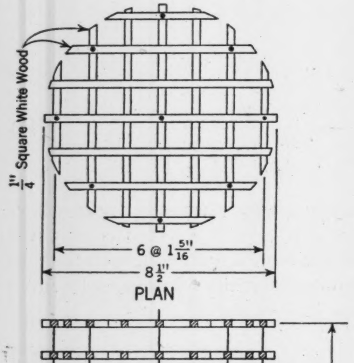

FIG. 5

Fig. 4 illustrates the material used in the experiments. This material, which was separated from the powder by sieves and a wind tunnel, was analyzed to determine the size and settling velocity distributions. The diameters of two hundred particles, which were chosen at random, were measured and the settling velocities in water at 10° C were then computed. In the computations the value of the drag coefficient was obtained from the equation by C. W. Oseen (16). The diameters varied from 0.138 mm to 0.216 mm and the corresponding settling velocities from 0.150 cm per sec to 0.344 cm per sec. The arithmetical average value of the settling velocity was 0.264 cm per sec. This value was used for w in all of the subsequent computations.

Suspensions of these particles in distilled water were used in all of the experiments. To prevent the particles from attaching themselves to air bubbles it was necessary to use a wetting agent. About 1 cu cm of an agent known as "Ultrawet No. 40" was used in each liter of the suspension. It was found that this amount had no measurable effect on the settling velocities of the particles.

Apparatus and Methods of Measurement.—The experimental setup was similar in its essentials to that used by Professor Rouse (6). In all of the runs the suspension was contained in a cylinder 9 in. in diameter by about 20 in. high. The mixing was accomplished by the lattice structure shown in Fig. 5. This was oscillated vertically in simple harmonic motion, thus producing an essentially uniform degree of mixing throughout the fluid. The cylinder was set in a thermostatically controlled water bath by which the temperature of the water in the cylinder was maintained at 10° ± 0.2° C.

The concentrations were measured by syphoning off samples of the suspension and obtaining the dry weight of the particles. In the sampling operation an amount equal to two or three times the volume of the siphon was wasted before the sample to be measured was collected. Each sample was collected in a 15-cc graduated centrifuge tube. When the lucite particles settled to the bottom of the tube they were picked up by an eye dropper and deposited in a small weighing dish which was then dried and weighed on an analytical balance.

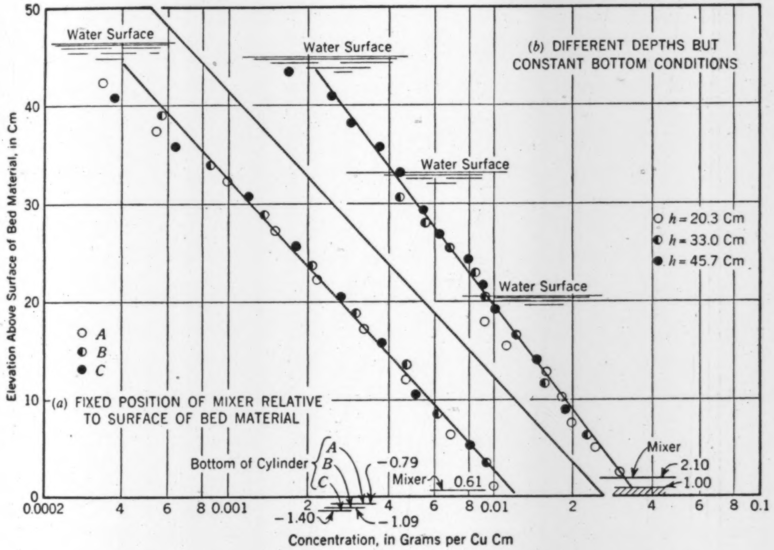

FIG. 6.—EQUILIBRIUM CONCENTRATIONS AT A MIXER SPEED OF 1.65 RPS

Procedure.—Measurements were made of the equilibrium concentrations with various total amounts of the powder, various mixing speeds, and various positions of the mixer with respect to the bottom of the cylinder. All of the results obtained were in agreement with the equilibrium distribution theory as expressed in Eq. 5*a*. Ample evidence of the validity of Eq. 5*a* has already been presented by Professor Rouse (6) and so all of the results will not be presented herein. Typical results are shown in Figs. 6 and 8. In each case the computed average thickness of the bottom deposit has been indicated after the equilibrium condition had been reached. The quantity of material on the bottom was determined as the difference between the volume in suspension and the total known amount used in the test. The volume in suspension was computed by Eqs. 6 and 7, the values of the necessary factors being taken directly from the linear plot. In these computations, the ratio of the dry weight to the volume occupied under water was taken as 1 g per 1.40 cu cm. This factor had been determined by measuring the volumes occupied by various known weights of material when settled out under water in a graduate.

Two runs were made for the purpose of checking the theory developed in the previous section. The first one was confined to the case in which the distribution of suspended matter at time $t = 0$ is defined by Eq. 5*b* and in which the pickup is zero. The solution for this case is given by Eq. 41 when A is taken as zero.

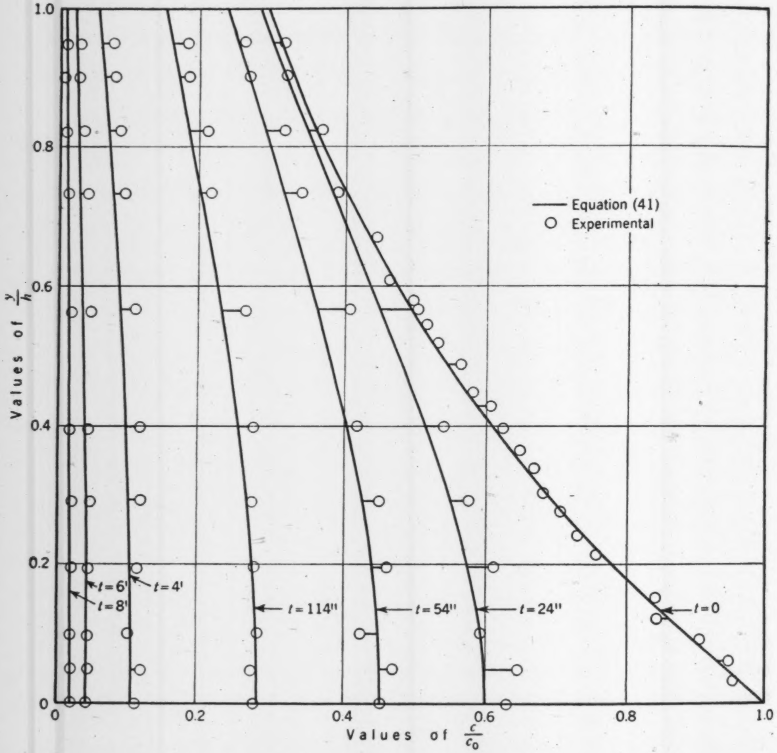

FIG. 7.—RUN IV. CONCENTRATION CHANGES WITH NO PICKUP

$\left(\frac{w}{\epsilon} = 0.030 \text{ cm}^{-1}; \text{and } h = 41.6 \text{ cm} \right)$

To satisfy these conditions physically, it was necessary to impose the condition of no pickup suddenly upon the equilibrium condition. This was accomplished by the setup shown diagrammatically in Fig. 9. The cylinder was supported at the top, as shown in Fig. 9(*a*), with a clearance of about 2 in. between the bottom of the cylinder and the floor of the water bath. The grid shown in Fig. 9(*c*) rested on the bottom of the cylinder and was attached to a framework external to the cylinder. Sufficient lucite was added to fill the grid completely and extend about 1 cm above the top of the grid. When the mixer was set in motion, the lucite above the grid was picked up and distributed according to the logarithmic law. This satisfied the condition for the original distribution.

To impose the condition of no pickup suddenly, the supporting bars at the top were swung outward, allowing the cylinder to drop to the floor of the water bath. This was accomplished in a fraction of a second. The particles of lucite settled through the grid into the space below, from which they could not be picked up. At various times after the cylinder was dropped, samples were drawn off through the siphon. After most of the material had settled, the cylinder was lifted back to its original position, the siphon was set to a different value of y, and the entire process was repeated.

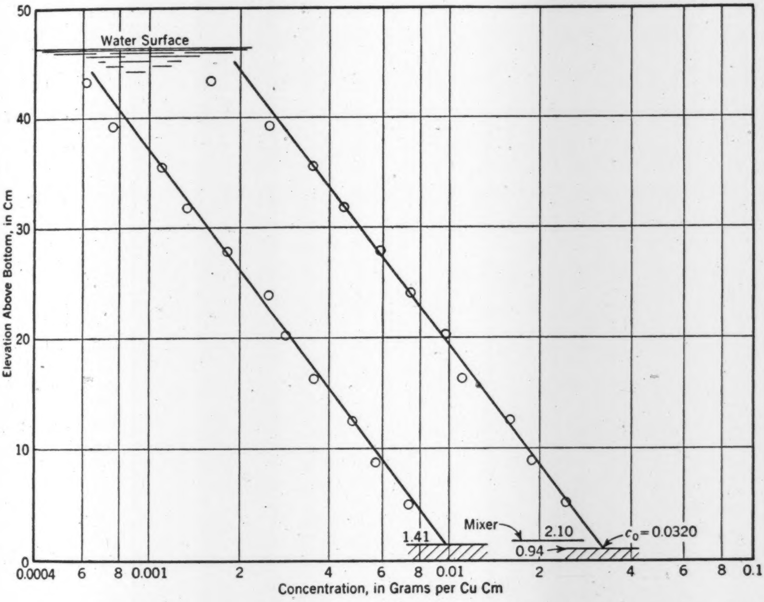

Fig. 8.—Initial and Final Equilibrium Concentrations; Run V; Mixer Speed, 1.65 RPS

The average sample size was about 14 cu cm and required about 6 sec for its collection. The volume of the siphon was found to be 13.8 cu cm and hence the time of passage through the siphon was also about 6 sec. To take this into account, the value recorded for the sampling time was 6 sec less than the time at which the center of the sample entered the collecting tube. A comparison between the theoretical and measured results is shown in Fig. 7.

The next run was made in order to check the theory for the case in which the pickup is not zero but has a constant value. An equilibrium condition was taken for the initial distribution of suspended matter, and another equilibrium condition with the same value of ϵ but with smaller absolute concentrations was taken as the final distribution.

plete turn had the effect of raising or lowering the cylinder 0.825 mm. Since the position of the mixer remained unchanged, the space between the mixer and the bottom of the cylinder was decreased or increased by the same amount.

A total of 660 cu cm of the lucite was used, and for the initial condition the cylinder was set so that the bottom was 14.4 mm below the lowest position of

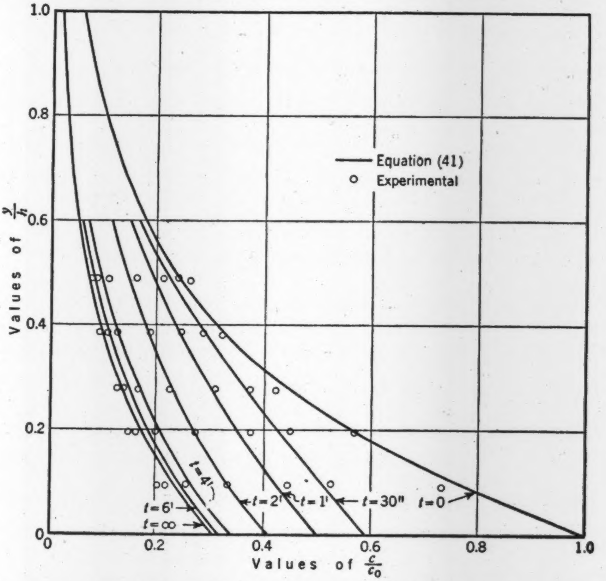

FIG. 11.—RUN V. CONCENTRATION CHANGES WITH CONSTANT RATE OF PICKUP $\left(\frac{w}{\epsilon} = 0.0638 \text{ cm}^{-1}; \text{ and } h = 45.2 \text{ cm}\right)$

the mixer. For the final condition the cylinder was lowered 6.60 mm, which was accomplished by making eight complete turns of the bolt. The measured concentrations for both of these conditions are shown in Fig. 8. Computations based on these curves show that the average depth of the bottom deposit was 9.4 mm in the initial condition and 14.1 mm in the final condition. Therefore, the distance between the surface of the bottom material and the lowest position of the mixer was 5.0 mm for the initial condition and 6.9 mm in the final condition.

To make the time study, it was necessary to impose upon the initial distribution a sudden rate of pickup equal to that in the final condition and to maintain this rate of pickup constant as the concentrations decreased. The results in Fig. 6(*a*) indicated that the rate of pickup depends upon the relative positions of the mixer and the surface of the bottom deposit, provided that the bottom is saturated. Therefore, to satisfy the pickup requirement, it was necessary to lower the cylinder suddenly until the distance between the lowest position of the mixer and the surface of the bottom deposit was equal to 6.9 mm, and then gradually to lower the cylinder so as to maintain this value as the suspended matter settled out.

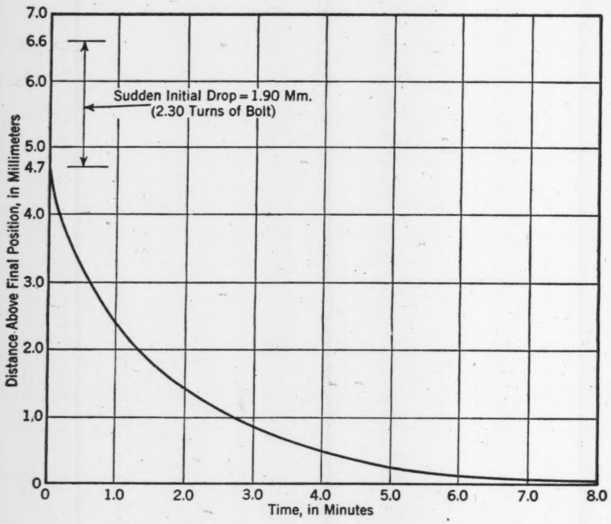

FIG. 12.—RATE OF DROP OF CYLINDER FOR RUN V

The sudden initial drop was 1.9 mm, which was equivalent to 2.3 turns of the bolt. From the theoretical concentration curve for any time after the initial drop (Fig. 11), the total amount of material deposited on the bottom up to that time could be computed, and hence the necessary total drop for the cylinder up to that time could be ascertained. By this means was prepared the curve shown in Fig. 12, which gives the necessary drop of the cylinder as a function of the time after the start. With the aid of Fig. 12, the time chart illustrated in Fig. 13 was prepared. In making the run, this chart was placed directly under the bolt and the bolt was turned so as to keep the pointer over the proper value of the time.

In the actual execution of the run, the services of two operators were required—one to turn the bolt and the other to take the samples. In turning the bolt, 3 or 4 sec elapsed before the initial turns could be made and the pointer brought up to its proper position on the chart. Once the proper position was reached, the pointer could be kept to within 2 or 3 sec of the proper value. After the 6-min sample had been taken, the pointer was turned to the final position and about 10 min were allowed to elapse before the final sample was drawn. After a complete series of samples had been taken for one value of y, the position of the siphon was changed and the entire procedure repeated. The results for this run are shown in Figs. 8 and 11.

FIG. 13.—VIEW OF TIME CHART USED IN RUN V

DISCUSSION OF THE RESULTS

The results show that the absolute magnitudes of the concentrations in suspension depend upon the quantity of material on the bottom and the hydraulic conditions at the bottom. The factors affecting the latter are the speed of the mixer and its position relative to the surface of the bottom deposit. The greater the mixer speed and the closer it is to the bed material, the greater are the concentrations of material in suspension.

The results demonstrate that, for a given speed of the mixer and a given position of the mixer relative to the bottom deposit, there is a definite concentration at any value of y, provided that the bottom is saturated. Fig. 6(a) shows conditions in which the depth of the bottom deposit varies and Fig. 6(b) shows conditions in which the depth of the fluid varies. In all cases, the concentration curves coincide when the bottom is saturated and the speed of the mixer and its position relative to the surface of the bed material are fixed.

In all of the experiments it was found that the final equilibrium concentrations were independent of the manner in which the lucite was added. In some cases all of the material had settled to the bottom before the mixer was set in motion; in other cases the mixer was already in motion as the material was added.

All of the results show that the absolute magnitude of the equilibrium concentration at a given elevation above the surface of the bed material is independent of the total amount of material in suspension and depends only upon the hydraulic conditions at the bed, provided that the bottom is saturated with the material. At the equilibrium condition, the rate of pickup must equal the rate of deposit, $w\,c$. Therefore, the results show that the rate of pickup of a given material is independent of the total amount of material in suspension and depends only upon the hydraulic conditions at the surface of the bed material. It seems logical to assume that the rate of pickup of a given material in a stream would also depend only upon the hydraulic conditions at the bed. Of course, in a natural stream the distribution of the particle sizes in the bed material would have to be taken into account.

The results of the time studies shown in Figs. 7 and 11 provide definite verification of the validity of Eq. 41. The trends of the experimental results follow those of the theoretical results quite closely. The validity of the assumptions regarding the boundary conditions as well as the validity of the time factor involved in the equation is demonstrated.

In Fig. 7 the plotted points lie consistently to the right of the theoretical curves, although in no case is the error any larger than 5% of the original bottom concentration. These results show that the rate at which the material settled was slightly less than the theoretical rate. Two factors are offered as an explanation of this. At the start of the run, when the cylinder was dropped, the effect on the suspension was the same as if the mixer had been suddenly lifted upward. This may have had the effect of transporting material upward so as to result in an original concentration at every value of y which was slightly greater than what was assumed. Probably most important, however, was the fact that the pickup was not absolutely zero as the material settled out, since the grid provided some surface on to which the particles could fall and from which they could be picked up again.

The results in Fig. 7 show quite conclusively that the concentration gradient at the surface is proportional to the magnitude of the surface concentration and that the gradient at the bottom is zero when there is no pickup. The results in Fig. 11 demonstrate that the concentration gradient at the bottom is constant when the pickup is constant. Verification of the formulas that express boundary conditions I and II at the surface and at the bottom is thereby obtained.

CONCLUSIONS

The principal conclusions that can be deduced from the experimental results may be summarized as follows:

1. Further evidence of the validity of the logarithmic law for the vertical distribution of sediment at the equilibrium condition is provided;
2. The equilibrium concentrations are independent of the method by which the material is added to the suspension;
3. Other things being equal, the equilibrium concentrations depend upon the amount of material available on the bottom, up to the point of saturation;
4. When the bottom is saturated with a given material, the equilibrium concentrations depend upon the hydraulic conditions at the bed;
5. The equilibrium concentration at any elevation above the bed is independent of the depth of the fluid provided that the bottom is saturated;
6. The rate of pickup for unsteady conditions is independent of the total amount in suspension and depends only upon the hydraulic conditions at the bed and the characteristics of the bed material, provided that the bottom is saturated with the material; and
7. The one-dimensional case of the theory of turbulent sedimentation for discrete particles is verified.

ACKNOWLEDGMENTS

This paper was condensed from a thesis presented by the writer in partial fulfilment of the requirements for the degree of Doctor of Science in Sanitary Engineering from the Massachusetts Institute of Technology, Cambridge, Mass., in October, 1941. Copies of this thesis are on file at Massachusetts Institute of Technology and the Engineering Societies Library. The experimental work was done in the Institute's Sanitary Engineering Laboratory. The writer gratefully acknowledges his indebtedness to the members of the staff of the Department of Civil and Sanitary Engineering for their interest and help throughout the work.

Special acknowledgment is due to Professor Camp, under whose direction the study was made, for his advice and encouragement during the study. P. C. Stein, Assoc. M. Am. Soc. C. E., gave many valuable suggestions and assisted in the preparation of some of the figures, and Prof. G. P. Wadsworth of the Department of Mathematics advised the writer concerning some of the mathematical aspects of the study.

APPENDIX 2

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

A = concentration at $y = 0$, $t = \infty$;
a = reference elevation for suspended-load function;
B = constant used in a function describing the initial distribution of suspended matter;
C = constant: C_1, C_2, C_3 = arbitrary constants; C_n = arbitrary constant in Eq. 32*b*;

---

[3] ASA—Z10.2—1942.

c = concentration of sediment in suspension: c_0 = concentration at $t = 0, y = 0$;
e = base of Naperian logarithms;
f = Weisbach-Darcy friction factor;
g = acceleration of gravity;
H_n = a function of h defined by Eq. 39b;
h = total depth of fluid;
k = a constant defined by Eqs. 21 and 24; when specifically defined, it is also used as a constant in the formula of a parabola (Eqs. 15);
l = mixing length;
n = any integer;
S = slope of energy gradient;
s = distance in any direction (see Eq. 2);
T = function of t;
t = time of settling;
V = mean velocity at a point;
$\overline{V}$ = mean velocity for the entire cross section;
v = instantaneous velocity at a point;
$\bar{v}$ = mean velocity at a point;
v' = fluctuation velocity at a point: $\bar{v}'$ = temporal mean value of the fluctuation velocity; $|\bar{v}'|$ = temporal mean value of the absolute magnitude of the fluctuation velocity;
W = total amount of sediment held in suspension per unit horizontal area;
w = settling velocity of the particles;
x = horizontal distance in the direction of flow;
Y = a function of y: Y_n = a function of y defined by Eq. 34;
y = elevation above surface of bed material;
z = exponent in a suspended-load function;
α = constant defined by Eq. 31;
β = proportionality factor;
ϵ = kinematic turbulence coefficient = $\beta|\bar{v}'|l$;
η = a function of $h\,\alpha$ defined in Eq. 31;
κ = von Kármán universal velocity distribution constant;
ρ = mass density of the fluid;
τ = intensity of fluid shear: τ_0 = intensity of fluid shear at $y = 0$.

DISCUSSION

A. M. GAUDIN,[4] ESQ.—A particularly significant attempt to analyze the problem of sedimentation under turbulent conditions is contained in the paper by Mr. Dobbins. The discussion of the distribution of particles in a vessel in which the turbulence varies along a vertical coordinate only is convincing indeed in the agreement of theory and practice. Of course, the broader problem of the distribution of particles in a flowing stream is what the author is looking toward, but has not yet undertaken to solve. It is to be hoped that this will be done in subsequent papers.

Systems in which particles of various sizes, specific gravities, and shapes occur simultaneously have been excluded from analysis; yet they represent the more usual condition. Further work should include such studies.

In concluding these very brief comments, the writer wishes to congratulate Mr. Dobbins for this well-documented and splendid contribution to the knowledge of the movement of solids in fluids.

JOHN S. MCNOWN,[5] JUN. AM. SOC. C. E.—It is a real pleasure to find an engineer who is both willing and able to carry through a difficult mathematical analysis of the type presented in this paper. The study of turbulence and sedimentation is an outstanding example of that unfortunately small phase of engineering in which a theoretical analysis leads to a complete solution. Despite the necessary simplifying assumptions and the tedium of the numerical computations, this approach doubtless will prove more valuable than empirical results from experimental data. Engineers must resort continually to empirical or trial-and-error methods, but scientific advancement must include satisfactory theoretical treatments.

As in so many physical problems, the definition and application of the proper boundary conditions present the most difficult part of this solution. The surface and bottom boundary conditions for combined liquid and solid motion are not only difficult to apply, but also difficult to predetermine. The surface conditions may be approximated by a plane surface with zero turbulence. However, as the author states, this condition is not accurate as the surface is generally irregular. Measurements of open-channel flow conducted by the writer at the St. Anthony Falls Hydraulic Laboratory at the University of Minnesota gave evidence of a turbulent velocity near the surface which was not small compared to turbulent velocities in other parts of the channel. In one instance the vertical component of the turbulent velocity in the upper 1% of the depth was as much as half the maximum vertical turbulence velocity occurring at the lower one-quarter point. The turbulent diffusion coefficient decreased near the surface because the mixing length decreased. Nevertheless, the concept of a zero turbulence coefficient at the surface does not agree with the physical picture of turbulent open-channel flow.

The artificial bottom conditions introduced by the author served nicely in furnishing a boundary condition that could be evaluated in the solution. For sediment transportation in open channels the accurate evaluation of this boundary condition provides the principal stumbling block to a solution of this troublesome problem. The relationships between bed load, suspended load, and the flow characteristics are dependent on this condition primarily.

---

[4] Dept. of Metallurgy, Mass. Inst. Tech., Cambridge, Mass.

[5] Research Associate, Div. of War Research, Univ. of California, San Diego, Calif.

The differential equation for this problem (Eq. 14*b*) is incomplete as witnessed by the lack of symmetry in x and y. The term, $\frac{\partial \epsilon_x}{\partial x} \frac{\partial c}{\partial x}$, should be added to the right-hand side of the equation. The derivation of Eq. 14*b* through the rather involved relationships expressed in Eq. 14*a* and Fig. 1 is less direct and, hence, more subject to errors of omission than a vector presentation of the same equations. Further simplification is obtained by expressing the relationships in two fundamental equations—the general expression for the current or transport in a turbulent medium and the equation of continuity. The vector current, **q** (of sediment in this case), is the vector sum of the field velocity, **u**, times the concentration and the turbulent diffusion which is the product of the gradient of the concentration and the coefficient of diffusion. Thus, in vector-operator form,

$$\mathbf{q} = \mathbf{u} c - \epsilon \operatorname{grad} c \text{ .... (42)}$$

The equation of continuity is expressed by equating the divergence of the current at any point to the rate of decrease of concentration with time, thus:

$$\operatorname{div} \mathbf{q} = - \frac{\partial c}{\partial t} \text{ .... (43)}$$

If the divergence of Eq. 42 is taken, the resulting expression is

$$\operatorname{div} \mathbf{q} = \operatorname{div} (\mathbf{u} c) - \operatorname{div} (\epsilon \operatorname{grad} c)$$

or,

$$\nabla \mathbf{q} = \mathbf{u} (\nabla c) - \nabla (\epsilon \nabla c) \text{ .... (44)}$$

if **u** is considered to be a constant. Combining Eq. 43 and Eq. 44 and performing the indicated operations for a two-dimensional problem, the equation may be written as follows:

$$\frac{\partial c}{\partial t} = - u_x \frac{\partial c}{\partial x} - u_y \frac{\partial c}{\partial y} + \frac{\partial \epsilon_x}{\partial x} \frac{\partial c}{\partial x} + \frac{\partial \epsilon_y}{\partial y} \frac{\partial c}{\partial y} + \epsilon_x \frac{\partial^2 c}{\partial x^2} + \epsilon_y \frac{\partial^2 c}{\partial y^2} \text{ ... (45a)}$$

The velocities u_x and u_y are the components of the field velocity tending to move the sediment continuously in the x-direction and y-direction. In the author's notation they are V, the stream velocity, and $- w$, the settling velocity, respectively. In the steady-state problem $\frac{\partial c}{\partial t} = 0$. The final equation to be compared with Eq. 14*b* is,

$$V \frac{\partial c}{\partial x} = w \frac{\partial c}{\partial y} + \frac{\partial \epsilon_x}{\partial x} \frac{\partial c}{\partial x} + \frac{\partial \epsilon_y}{\partial y} \frac{\partial c}{\partial y} + \epsilon_x \frac{\partial^2 c}{\partial x^2} + \epsilon_y \frac{\partial^2 c}{\partial y^2} \text{ .... (45b)}$$

The only difference between Eqs. 14*b* and 45*b* is the added term $\frac{\partial \epsilon_x}{\partial x} \frac{\partial c}{\partial x}$, as pointed out in the foregoing. Admittedly, the variation of ϵ with x is not important in the problem under consideration, and would introduce no change in the simplified form, Eq. 17*b*. This derivation and the correction have been presented to give complete generality to the basic equation, so far as intended, and to show the nicety of the vector-operator derivation.

Unfortunately, this problem entails a long and involved mathematical solution, even after a number of simplifying assumptions. The complications of the boundary conditions and parameter variations in most practical problems are formidable. In many cases some simplifications of the numerical computations would be justifiable, particularly if the boundary conditions and the parameter values were not determined accurately. The solution of Eq. 30 may be simplified for small values of $\frac{w\,h}{2\,\epsilon}$. The first value of α could be determined by trial and error or graphically, and all others could be approximated by the relationship,

$$\alpha_n = n\,\pi \quad \text{(46)}$$

with n taking the values of 1, 2, 3, $\cdots$ as far as required. The discrepancy between this simplified solution and that used by the author was compared by the writer in a similar set of computations and found to be only a few per cent.

The author has not mentioned direct measurements of the settling velocity of the particles. Such measurements would give a further check on the degree of accuracy of the results. The values computed from predetermined coefficients may be sufficiently accurate, but the opportunity for the direct measurement of a critical parameter, such as the settling velocity, should be taken wherever possible. The use of an arithmetic mean value of the settling velocities for values of w ranging from 0.150 cm per sec to 0.344 cm per sec is of doubtful accuracy. This range of more than a factor of two becomes magnified for large time values because of the nature of the equation. The concentration of smaller particles after a comparatively long time may well have been many times greater than the concentration of the larger particles. Any information on such a change in the statistical spread of the various sizes would be interesting in this connection. It is difficult to observe in the author's results whether this or other effects introduced errors into the computations at large values of the time variable. A semilogarithmic plot for Fig. 7 and Fig. 11 (as in Fig. 8) would enable the reader to compare the theoretical curves with the plotted points more readily.

An interesting by-product of this experiment is the indirect determination of turbulence parameters. The data available serve to evaluate the turbulence diffusion coefficient, ϵ. From the data at the bottom of Fig. 7 and Fig. 11 and the settling velocity, $w = 0.264$ cm per sec, ϵ can be computed. In the two instances presented $\epsilon = 8.8$ and 4.1 cm per sec. The comparison between these values and the quantities which determine the mixing length and the root-mean-square turbulent velocity might be of interest. The grid spacing, the vertical displacement, and the velocity of the lattice structure are the values most likely to be effective in determining ϵ. In a simplified form this type of experiment could be used to study the effect of the mechanical motion on the scale of turbulence. The determination of the concentration of sediment at various levels could be compared with the steady-state Eq. 5*a*. Good agreement with this equation would furnish a constant value of ϵ. A lack of agreement could be analyzed from the standpoint of a variable ϵ.

H. A. EINSTEIN,[6] ASSOC. M. AM. SOC. C. E.—Ostensibly resulting from the study of sedimentation problems in settling basins, this paper is especially interesting to the hydraulic engineer who is not familiar with this special problem. Artificial settling basins, as studied and applied by the sanitary engineer, usually are characterized by very small average flow velocities of the water. Professor Camp (2) showed that under certain circumstances an increase of turbulence in such basins will shorten the settling time if this additional mixing affects coagulation thus increasing, materially, the settling velocity of small particles. The hydraulic engineer studying sedimentation in natural streams finds those conditions only in rare cases. Usually the turbulent mixing in natural streams is sufficient to prevent the clay from settling independently of the stage of flocculation. In many special cases, however, where high sediment concentration and salt content favor flocculation, this effect may explain otherwise incomprehensible situations.

Most significant in Mr. Dobbins' paper is the emphasis given to what he calls "pickup"—the exchange of particles between bed and suspension. In another connection (17), the writer has showed the paramount importance of this same exchange of particles in the description of bed-load movement, and probably this same exchange or pickup will some day make it possible to calculate the rates of bed material carried in suspension without the use of any concentration measurements.

In his experiments Mr. Dobbins used, exclusively, "artificial turbulence," that is, turbulence created by a system of baffles rather than by friction along the sediment deposit. The intensity of the resulting turbulence is not measured, and, therefore, no comparison with conditions in a natural river is possible. As a check of the formulas, the experiments are excellent and prove the formulas to be correct although somewhat complicated for practical use. The exceptionally clear presentation of this intricate subject makes Mr. Dobbins' paper an outstanding contribution to the literature on sedimentation in general.

THOMAS R. CAMP,[7] M. AM. SOC. C. E.—A significant contribution to current knowledge of sedimentation principles, this paper demonstrates clearly that suspended sediment is not held in suspension in a turbulent stream; but rather that it is settling out continuously and is being thrown back continuously into the stream by scour from the bottom. The concentration of suspended matter at any depth in a stream at equilibrium is thus shown to depend primarily upon the rate of scour from the bottom. When the rate of scour is equal to the rate of settling out, equilibrium prevails at all levels. When the rate of scour exceeds the rate of settling out, the concentration is increasing at all depths. When the rate of scour is less than the rate of settling out, the stream is clearing. If scour is prevented, the stream will clear completely; but the time required for clearing depends upon the settling velocity of the particles, the depth, and the magnitude of the turbulence.

---

[6] Hydr. Engr., SCS, U. S. Dept. of Agriculture, Greenville, S. C.

[7] Associate Prof., San. Eng., Mass. Inst. Tech., Cambridge, Mass.

The equilibrium condition characterized by Eqs. 3 and 4 has been widely used in the study of suspended-load distribution. It has been applied also to the measurement of evaporation of moisture from land and water surfaces (18), and to the movement of sand dunes by wind (19). In the light of Mr. Dobbins' studies, it is evident that, in all three problems, the equilibrium condition is only approximated in nature. The suspended matter in a stream and the sand in the air will be at the equilibrium concentration only when the rate of pickup equals the rate of settling out. The moisture in the air will be at the equilibrium concentration only when the rate of transport upward is the same across all horizontal planes.

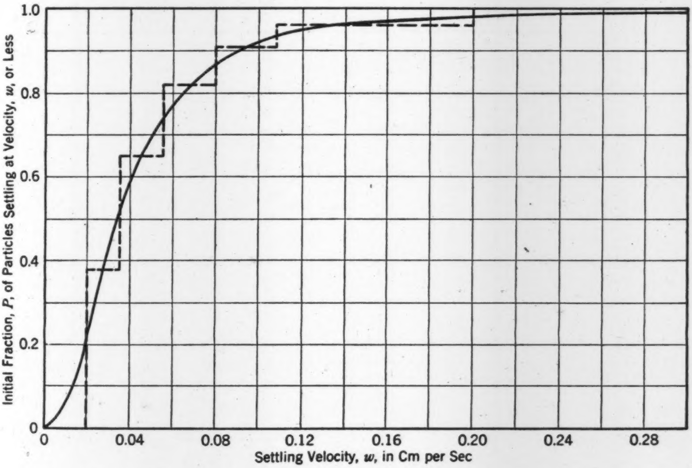

FIG. 14.—SETTLING VELOCITY ANALYSIS OF SUSPENSION OF DISCRETE PARTICLES

The studies described by Mr. Dobbins were undertaken as a part of a larger program aiming at a rational approach in the design of settling tanks. In a settling tank the rate of scour from the bottom is always less than the rate of settling out. In most types of settling tanks, there should be no scour from the bottom if the tank is functioning properly. The effect of turbulence is to retard the rate of clearing. The immediate objective of the author's studies was to obtain some estimate of the magnitude of this retarding effect.

Eq. 41 is an expression for the concentration at any height y and any time t for the one-dimensional case, the initial concentration being uniformly distributed and equal to c_0 from top to bottom. This corresponds to a value of ∞ for the mixing coefficient ϵ at the entrance to a settling tank, followed immediately by a finite value of ϵ within the tank. It is convenient to assume a uniform distribution of suspended matter at the start in order to compare the removal with that obtained under similar conditions but in the absence of turbulence.

In the absence of turbulence and scour, starting with uniform distribution of suspended matter, the removal after any time t of all particles whose settling velocity w is less than w_o is

$$r = \frac{w}{w_o} \qquad (47)$$

in which $w_o = \frac{h}{t}$ = the "overflow rate." In the sanitary engineering field, the "overflow rate" is usually defined as the discharge per unit of surface area. It is also the settling velocity required for a particle to settle throughout the depth h in time t. Therefore all particles with settling velocities exceeding w_o will be 100% removed in time t.

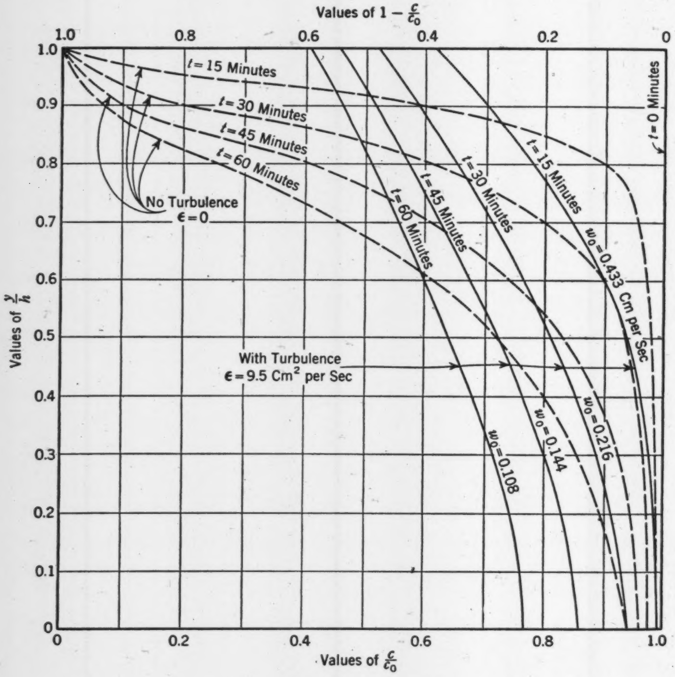

FIG. 15.—EFFECT OF TURBULENCE IN TANK 12.8 FT DEEP UPON SETTLING OF SUSPENSION OF FIG. 14

In the absence of scour, A is zero in Eq. 41. For this condition, Eq. 41 can be rewritten in the following dimensionless form:

$$\frac{c}{c_0} = \frac{w\,h}{2\,\epsilon}\,e^{i} \sum_{n=1}^{n=\infty} \frac{(h\,\alpha_n)^2\,H_n\,Y_n\,e^{-j}}{\left[\left(\frac{w\,h}{2\,\epsilon}\right)^2 + (h\,\alpha_n)^2 + \frac{2\,w\,h}{2\,\epsilon}\right]\left[\left(\frac{w\,h}{2\,\epsilon}\right)^2 + (h\,\alpha_n)^2\right]} \qquad (48)$$

in which, to simplify typography,

$$i = \frac{w\,h}{2\,\epsilon}\left(1 - \frac{y}{h}\right) \dots\dots\dots\dots (49a)$$

and

$$j = \left[\left(\frac{w\,h}{2\,\epsilon}\right)^2 + (h\ \alpha_n)^2\right] \frac{1}{\frac{2\,w\,h}{2\,\epsilon}} \frac{w}{w_o} \dots\dots\dots\dots (49b)$$

The relative concentration $\frac{c}{c_0}$ in Eq. 48 is a function of only three independent variables, $\frac{y}{h}$, $\frac{w\,h}{2\,\epsilon}$, and $\frac{w}{w_o}$, all of which are dimensionless.

The application of Eq. 48 to a suspension of particles of varying settling velocity requires that the analysis of the suspension in terms of settling velocity be known. Fig. 14 is a typical settling-velocity analysis of a suspension of discrete particles. In order to apply Eq. 48, the suspension should be fractionated as shown by the broken line. The equation is applied separately to each fraction, assuming that all particles in each fraction have the same settling velocity as shown; and the total relative concentration then is computed by adding the fractional values of $\frac{c}{c_0}$. Fig. 15 shows the results of such a computation. The corresponding values of $\frac{c}{c_0}$ in the absence of turbulence are shown by broken lines for comparison.

The average relative concentration throughout the depth h may be computed from the integral $\int_0^1 \frac{c}{c_0}\ d\left(\frac{y}{H}\right)$ in which the value of $\frac{c}{c_0}$ is taken from Eq. 48. This integral is evaluated readily. The removal from suspension by settling in time t is the difference between this integral and the initial concentration. Since the relative initial concentration must be taken at unity throughout the depth h, the relative removal with turbulence is

$$r = 1 - 8\left(\frac{w\,h}{2\,\epsilon}\right)^2 e^{(w\ h)/(2\ \epsilon)}$$

$$\times \sum_{n=1}^{n=\infty} \frac{(h\,\alpha_n)^2\,H_n\,e^{-i}}{\left[\left(\frac{w\,h}{2\,\epsilon}\right)^2 + (h\,\alpha_n)^2 + \frac{2\,w\,h}{2\,\epsilon}\right]\left[\left(\frac{w\,h}{2\,\epsilon}\right)^2 + (h\,\alpha_n)^2\right]^2} \dots\dots (50)$$

The term Y_n which appears in Eq. 48 has been eliminated in Eq. 50 by integration over the depth h. The relative removal in Eq. 50 is a function of only two independent variables, $\frac{w\,h}{2\,\epsilon}$ and $\frac{w}{w_o}$, both of which are dimensionless.

Numerical computations by means of Eqs. 48 and 50 are extremely tedious and cumbersome. Some problems of practical significance require fifteen or more terms for convergence of the series. Moreover, for such problems, the graphical evaluation of $h\,\alpha$ as illustrated by the author in Fig. 3 is not sufficiently accurate. It is convenient, therefore, to have a graph for solution of numerical problems; and the writer has prepared such a graph for Eq. 50. Fig. 16 is a dimensionless plot of r against $\frac{w\,h}{2\,\epsilon}$ for various values of $\frac{w}{w_o}$. The successive values of $h\,\alpha_n$ required for each computed point on this graph were determined to six decimal places by trial-and-error solutions of Eq. 31. Convergence of the series is rapid for low values of $\frac{w\,h}{2\,\epsilon}$, only one term being required for a value of 0.1. However, fourteen terms were required for $\frac{w\,h}{2\,\epsilon} = 30$, and no solution was practicable for $\frac{w\,h}{2\,\epsilon} = 100$.

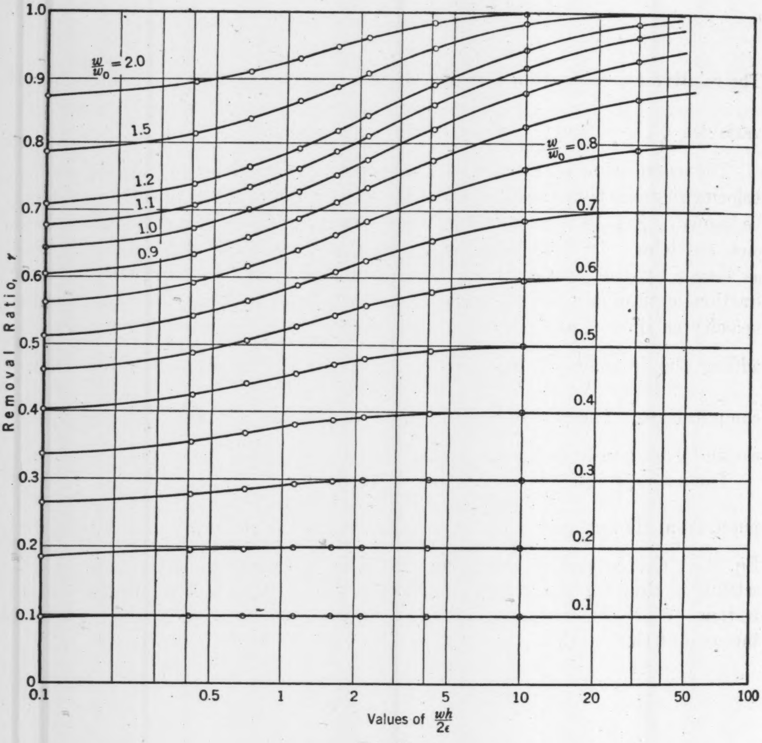

Fig. 16

The effect of turbulence in retarding settling for the one-dimensional case is apparent from Fig. 16. When turbulence is relatively great with a high value of ϵ, the value of $\frac{w\,h}{2\,\epsilon}$ is low and removal is reduced. For example, for particles that would be just 100% settled without turbulence (that is,

$\left.\frac{w}{w_o} = 1.0\right)$, the removal is only 64% if $\frac{w\,h}{2\,\epsilon} = 0.1$; but it is 72% if $\frac{w\,h}{2\,\epsilon} = 1.0$; and it is 94% if $\frac{w\,h}{2\,\epsilon} = 40$. The effect of turbulence on the settling out of particles is much less if the removal is less—that is, for low values of $\frac{w}{w_o}$.

Eqs. 48 and 50 and Fig. 16 are correct solutions for only the one-dimensional case. However, they may be used for two-dimensional flow in a stream or settling tank to obtain approximate solutions. The following bold assumptions are required in the adaptation to two-dimensional flow:

1. The fluid velocity is the same at every point in the channel; and
2. The mixing coefficient ϵ has the same value at every point in the channel.

By reference to Eq. 16*b*, it will be noted that the second assumption corresponds to a parabolic velocity distribution as illustrated by Fig. 2. Obviously, then, the two assumptions are contradictory; but they permit the use of Eqs. 17*b* and 17*c*, the only form of the general differential equation for which a solution has been obtained.

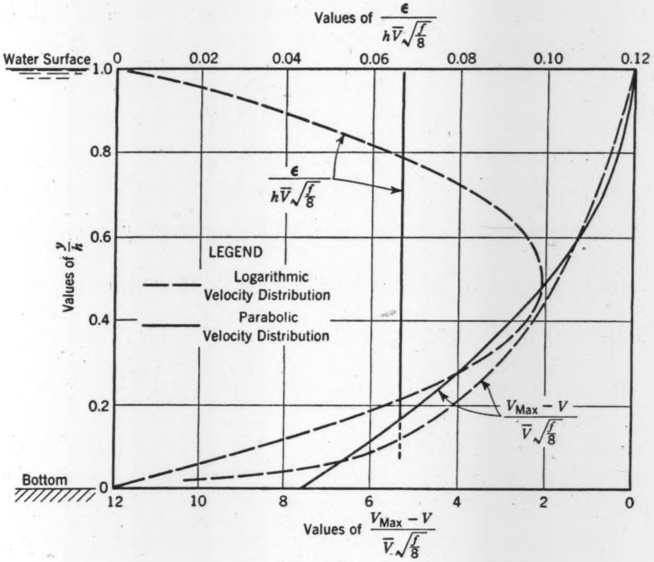

FIG. 17

The value of ϵ at any height y for two-dimensional open-channel flow and the logarithmic velocity distribution is given by Eq. 11, which may be rewritten in dimensionless form as follows:

$$\frac{\epsilon}{h\,\bar{V}\,\sqrt{\frac{f}{8}}} = \kappa\,\frac{y}{h}\left(1 - \frac{y}{h}\right) \qquad (51)$$

This value of ϵ and the corresponding velocity distribution are shown with broken lines in Fig. 17. The mean value of ϵ over the depth h is given by

$$\frac{\epsilon}{h\,\bar{V}\sqrt{\frac{f}{8}}} = \frac{\kappa}{6} = 0.0667 \ldots\ldots\ldots\ldots\ldots\ldots (52)$$

in which the value of κ is taken at 0.4. Eq. 52 is shown by the solid vertical line in Fig. 17. If this value of ϵ is assumed to obtain from top to bottom, the corresponding parabolic velocity distribution is as shown by the solid curve in Fig. 17.

The value of $\frac{w\,h}{2\,\epsilon}$ for two-dimensional open-channel flow may be expressed in terms of the mean velocity of the stream by means of Eq. 52 as follows:

$$\frac{w\,h}{2\,\epsilon} = \frac{3\,w}{\kappa\,\bar{V}\sqrt{\frac{f}{8}}} = 7.5\,\frac{w}{\bar{V}\sqrt{\frac{f}{8}}} \ldots\ldots\ldots\ldots\ldots\ldots (53a)$$

Also, since by similar triangles $\frac{w_o}{\bar{V}} = \frac{h}{L}$ (in which L is the length of travel at the mean velocity $\bar{V}$ in time t)—

$$\frac{w\,h}{2\,\epsilon} = \frac{3}{\kappa\sqrt{\frac{f}{8}}}\,\frac{h}{L}\,\frac{w}{w_o} = \frac{7.5}{\sqrt{\frac{f}{8}}}\,\frac{h}{L}\,\frac{w}{w_o} \ldots\ldots\ldots\ldots\ldots (53b)$$

As an example, let it be required to find the effect of turbulence on the settling of particles which would be just 70% removed $\left(\frac{w}{w_o} = 0.70\right)$ in the absence of turbulence in a 200-ft stretch of tank 10 ft deep $\left(\frac{h}{L} = 0.05\right)$ if $f = 0.032$. From Eq. 53*b*, $\frac{w\,h}{2\,\epsilon} = 4.15$. From Fig. 16, it is found that the removal is 65.7%—a reduction due to turbulence of $\frac{4.3}{70}$ or 6.1% in the removal.

As another example, let it be required to find the effect of turbulence on the removal of particles whose settling velocity w is 0.22 cm per sec, settling to take place in a 200-ft settling zone, 10 ft deep in which the mean velocity is 10 ft per min and f is 0.032. The detention period, t, is $\frac{200}{10} = 20$ min or 1,200 sec. The overflow rate $w_o = \frac{10 \times 30.48}{1{,}200} = 0.254$ cm per sec. The removal in the absence of turbulence is $\frac{w}{w_o} = \frac{0.22}{0.254} = 0.866$ or 86.6%. From Eq. 53*a*, $\frac{w\,h}{2\,\epsilon} = 7.5\,\frac{0.22}{10 \times \frac{30.48}{60}\sqrt{\frac{0.032}{8}}} = 5.13$. From Fig. 16 it is found that the removal is about 77.2%, the effect of turbulence being to reduce the removal about 10.8%.

Mr. Dobbins has tackled a difficult problem with ingenuity and resourcefulness. He has overcome many obstacles in mathematical analysis and experimental technique and has evolved a sound answer which must serve as a basis for future work in this field. The writer contributed the idea which initiated this program and helped with advice from time to time. It is gratifying to have been associated with the author in this small way. Even the kibitzer is pleased when the hand is won.

GARBIS H. KEULEGAN,[8] ESQ.—The statement of the boundary conditions relating to the solution of the differential equation of the one-dimensional case requires examination.

Apparently it is the author's understanding that the solution of the basic equation, Eq. 17*c*, requires four boundary conditions. The equilibrium distribution which finally is established is taken as one of these. Obviously, the final disposition of a physical process is a consequence and cannot be preassigned as a boundary condition. Indeed the description of the final disposition must result from the analysis itself. Actually, only three conditions are necessary for the desired solution.

The mathematical expression of the argument is much simplified if Eq. 17*c* is transformed into a relation involving dimensionless quantities only. Suppose that t is measured in terms of T, and y in terms of h; thus, let $\tau = \frac{t}{T}$; $\eta = \frac{y}{h}$; $T = \frac{h^2}{\epsilon}$, and $\beta = \frac{w}{h\,\epsilon}$. Then, Eq. 17*c* takes the form

$$\frac{\partial c}{\partial \tau} = \frac{\partial^2 c}{\partial \eta^2} + \beta \frac{\partial c}{\partial \eta} \text{......................} (54)$$

Suppose that a solution is sought, subject to the following three boundary conditions:

First, the transport of the material across the upper surface into the liquid below is brought about in a preassigned manner. Mathematically,

$$\frac{\partial c}{\partial \eta} + \beta\, c = \phi(\tau); \qquad \eta = 1, \quad \tau > 0 \text{................} (55)$$

Second, the rate of pickup from the bottom is controlled in a preassigned manner; or, what is the same thing, the gradient of concentration at the bottom is controlled in a preassigned manner. Mathematically,

$$\frac{\partial c}{\partial \eta} = \theta(\tau); \qquad \eta = 0, \quad \tau > 0 \text{................} (56)$$

Third, the initial concentration is specified. Mathematically,

$$c = f(\eta); \qquad 0 > \eta > 1, \quad \tau = 0 \text{..................} (57)$$

It will be noted that the conditions assumed are of the most general type.

---

[8] Physicist, National Bureau of Standards, Washington, D. C.

If a solution of Eq. 54 conforms to the end conditions, Eqs. 55, 56, and 57, then this solution is unique.

In order to prove this statement, a theorem of expansion is needed. Consider the sequence of functions

$$\Theta_n = 2\,\delta_n \cos \delta_n\,\eta + \beta \sin \delta_n\,\eta; \qquad n = 1, 2, \cdots \quad \ldots\ldots\ldots(58)$$

in which δ_n is one of the positive roots of the relation

$$4\,\delta\,\beta \cos \delta = (4\,\delta^2 - \beta^2) \sin \delta \ldots\ldots\ldots\ldots\ldots\ldots(59)$$

These functions have the properties

$$\int_0^1 (\Theta_n)^2\, d\eta = \frac{(2\,\delta_n + \beta)^2}{2} \ldots\ldots\ldots\ldots\ldots\ldots(60a)$$

and

$$\int_0^1 \Theta_n\,\Theta_m\, d\eta = 0; \qquad n \neq m \ldots\ldots\ldots\ldots\ldots\ldots(60b)$$

Because of these properties (ordinarily referred to as the properties of orthogonality) any bounded function $F(\eta)$ may be expanded in terms of Θ_n in the interval, $0 \overline{\overline{<}} \eta \overline{\overline{<}} 1$, provided that, if the function has discontinuities, these are finite in number. Mathematically,

$$F(\eta) = \sum (C_n\,\Theta_n) \ldots\ldots\ldots\ldots\ldots\ldots(61)$$

in which $C_n = \dfrac{2}{(2\,\delta_n + \beta)^2} \displaystyle\int_0^1 F(\eta)\,\Theta_n\, d\eta$. In addition to the discontinuities, the expansion may fail at the end points, $\eta = 0$ and $\eta = 1$, depending on the character of F. Similar and equivalent expansions were used by the author.

Now suppose that the solution of Eq. 54, conforming to the boundary conditions, Eqs. 55, 56, and 57, is not unique. Let C_1 be one solution and C_2 another. Consider the difference,

$$q = C_1 - C_2 \ldots\ldots\ldots\ldots\ldots\ldots(62)$$

Since C_1 and C_2 individually satisfy the boundary conditions, Eqs. 55, 56, and 57, it can be shown that q satisfies certain simpler boundary conditions, which are derived from Eqs. 55, 56, and 57:

$$\frac{\partial q}{\partial \eta} + \beta\, q = 0; \qquad \eta = 1, \quad \tau > 0 \ldots\ldots\ldots\ldots(63a)$$

$$\frac{\partial q}{\partial \eta} = 0; \qquad \eta = 0, \quad \tau > 0 \ldots\ldots\ldots\ldots(63b)$$

and

$$q = 0; \qquad 0 \overline{\overline{<}} \eta \overline{\overline{<}} 1, \quad \tau = 0 \ldots\ldots\ldots\ldots(63c)$$

Again, since C_1 and C_2 individually satisfy the linear differential equation, Eq. 54, q also satisfies the same equation,

$$\frac{\partial q}{\partial \tau} = \frac{\partial^2 q}{\partial \eta^2} + \beta\,\frac{\partial q}{\partial \eta} \ldots\ldots\ldots\ldots\ldots\ldots(64)$$

Obviously, the solution of Eq. 64 conforming to the boundary conditions, Eqs. 63*a* and 63*b*, is

$$q = \sum (C_n \, e^{\gamma\tau} \, e^{-0.5\beta^2\eta} \, \Theta_n) \ldots\ldots\ldots\ldots\ldots\ldots (65)$$

in which $\gamma = -\frac{\beta^2}{4} - \delta^2$. It remains to ascertain C so that the boundary condition given by Eq. 63*c* is also satisfied. When $\tau = 0$,

$$q = \sum (C_n \, e^{-0.5\beta^2\eta} \, \Theta_n) \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

Since $q = 0$ at the points $\eta = 0$ and $\eta = 1$, an application of the theorem underlying Eq. 61 yields

$$C_n = 0; \qquad n = 1, 2, \cdots \quad \ldots\ldots\ldots\ldots\ldots (67a)$$

and, therefore,

$$q = 0; \qquad \tau > 0 \ldots\ldots\ldots\ldots\ldots\ldots (67b)$$

Accordingly $C_1 = C_2$. This proves the proposition that the solution of Eq. 54 conforming to the boundary conditions, Eqs. 55, 56, and 57, is unique.

Thus, the fourth boundary condition stated by the author is redundant for the problem since the solution finally arrived at is correct. That the solution is correct may be established by modifying the arguments of the author so that only the first three conditions are used to obtain the final solution; or another method of solution may be adopted, using the same three conditions and leading to the same results. Both of these methods were followed by the writer.

C. W. THORNTHWAITE,[9] ESQ.—In connection with studies directed toward the objective of measuring the transport of moisture from a natural surface into the atmosphere, through the medium of turbulent mass exchange, the writer and his associates have found it necessary to make detailed and careful observations of the variation of wind velocity with height in the layer within 30 ft of the ground (20)(21)(22). To obtain observations that would reveal the true nature of the wind gradient it was first necessary to select anemometers that were identical as to starting and stopping speeds, and running speed at all velocities. A number of matched anemometers were mounted one above the other on a 28-ft tower and connected electrically to a photographic recorder that makes simultaneous recordings of all at 15-min intervals.

The data indicate that the familiar logarithmic law of wind velocity is of restricted validity. This law applies very well when the temperature lapse rate is adiabatic (or within this thin layer, isothermal), but it fails when the lapse rate is superadiabatic and also at times of inversions. Gradients of wind movement for a series of hours on July 25 and 26, 1942 (Fig. 18), illustrate the dependence of wind distribution on stability. The data are plotted on a semilogarithmic scale; in order for the logarithmic law to be verified the data for individual hours would form straight lines; but only two series made in the evening of July 25 (lines F and G) approach straight lines. The daytime observations plot along lines having concave curvature; those made near noon show the greatest departure from a straight line. Observation J made near midnight displays strong convex curvature. This is the only one of the series in the figure that does so, but it represents a tendency that is characteristic of most observations made in the early hours of the morning before sunrise.

---

[9] Chf., Climatic and Physiographic Div., SCS, U. S. Dept. of Agriculture, Washington, D. C.

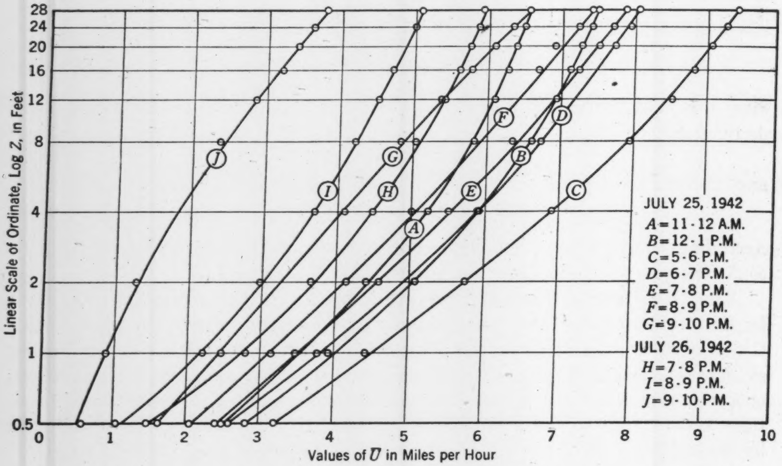

Fig. 18.—Gradients of Wind Movement

These observations suggest a reasonable physical picture of turbulent mixing in the atmosphere. When the thermal lapse rate is adiabatic, as for brief periods in the morning and again in the evening, and the logarithmic law is fulfilled, Prandtl's theory (Eq. 1) is valid, and the coefficient of turbulent mixing, designated ϵ by the author, may be obtained by Eq. 9. Turbulent mixing is mechanical only.

In the middle of the day, when thermal convection is active, convective turbulence is superimposed upon mechanical turbulence and ϵ becomes greater—possibly much greater than is indicated by Eq. 9. The concave curvature of the wind gradients is a consequence of this increase in the coefficient of turbulent mixing. As momentum is transported downward more actively the tendency for differences in velocity in adjacent layers to be equalized increases, and the wind profile becomes more nearly vertical except very close to the ground surface.

At night when the ground, having been cooled by radiation, cools the adjacent air, the lowest layer of air becomes cooler than that above it and a stable lapse rate is created. The air next to the ground, being cooler, is denser than that above and, if moved mechanically upward into a faster moving layer, would tend to move down again instead of mixing with the air in the new environment. In this instance ϵ becomes less than is indicated by Eq. 9. Momentum is transported downward less actively, the tendency for velocity differences in adjacent layers to be equalized diminishes, and the velocity profile departs more than ever from the vertical except within a foot or two of the ground.

This physical picture of the variation of ϵ with stability is in accord with the well-known phenomenon that the diurnal march of wind velocity a few hundred feet aloft (on the top of the Eiffel Tower, for example) is opposite to that close to the ground.

The suspension of sediment in water will tend to make the fluid more stable. The experiments by Mr. Vanoni (7) confirm this. Mr. Vanoni's semilogarithmic plots of velocity profiles at the center of a flume depart quite widely from the logarithmic law and display the same convex curvature that has been observed in a stable atmosphere. This is contrary to his statement that, "The data follow the logarithmic law very closely except near the bottom where the measured velocities exceed those predicted from the law" (7*a*).

Mr. Vanoni reports that the velocity of sediment laden water is greater than that of clear water, which fact he correctly ascribes to a decrease in ϵ. He thinks that the decrease in ϵ is due to a decrease in the value of K, the von Kármán universal turbulence constant. Of course, ϵ will decrease with increasing density (see Eq. 9) but at least in the free air density differences in the profile of stable air are so small that their effect on ϵ must be negligible. The increase of density due to sediment suspension likewise falls far short of being sufficient to account for the decrease in ϵ.

The data plotted in Fig. 7 suggest a variation in ϵ from top to bottom of the tank that may be due to a changing value of the mixing length with changing sediment concentration. Turbulence was imposed artificially by a "lattice structure" and the author assumes that the fluid was mixed uniformly. Actually the sediment concentration near the bottom of the cylinder was about three times as great as at the top at the beginning of the experiment. Therefore, in line with Mr. Vanoni's findings, the value of ϵ near the bottom would be less and that near the top would be greater than the mean value. Then, when the apparatus is set in motion, mixing near the bottom is less than expected and the sediment concentration does not diminish at the rate called for by Eq. 41. Conversely, near the top of the cylinder, mixing is greater and the concentration of sediment is in excess of that predicted. Only when the sediment is nearly uniformly distributed through the fluid do the author's data verify his theory.

An interesting experiment would be to simulate, in a flume, the unstable conditions that prevail in the atmosphere near the ground on warm sunny days. Heating coils in the bottom of the flume would serve the purpose, and it is to be expected that plots of the velocity gradient on semilogarithmic paper would display the same concave curvature that has been observed in the wind velocity profiles.

The writer is of the opinion that Prandtl's theory of turbulence will need to be modified before it can be applied to the study of sediment transport in streams, since there seems to be considerable evidence that the mixing length varies with height in a sediment laden fluid, according to a law that is different from the one that has been applied successfully to a fluid that is homogeneous throughout.

A. A. KALINSKE,[10] ASSOC. M. AM. SOC. C. E.—By analyzing an especially difficult problem mathematically and then testing the validity of his development by making experiments under certain controlled boundary conditions, the author has presented a very fine contribution. His analyses and experiments lead him to certain definite conclusions. These all seem to be warranted by the facts at hand and the writer is in entire agreement with them. Of particular significance to the writer are the author's conclusions relating to the influence of the bed composition on the suspended material. This item is of basic importance in developing a relation among the absolute value of suspended material concentration, the bed composition, and the hydraulic conditions at the bed.

In connection with the author's assumption of similarity in turbulent flow between the momentum and sediment transfer processes ($\beta = 1$) the results of further studies that have been made along this line may be of interest (23). A detailed study was made of the value of the mass-transfer coefficient in turbulent flow in open channels, and its directly measured value was used to calculate sediment distribution curves. The calculated sediment distribution curves agreed very well with actual sediment concentration measurements. The turbulence diffusion coefficients were measured by determining the spread in the turbulent flow of an injected mixture of hydrochloric acid and alcohol, the proportions being adjusted so the density of the mixture was equal to that of the water. Point samples of water were taken to determine the spread of the mixture, and the concentration of the chlorides in the samples was determined by titration. This provided a quick and accurate means of obtaining data for direct measurement of the turbulence diffusion coefficient.

The author's comments on the "pickup" of material from the bed and the relation between suspended and bed material were of considerable interest to the writer. This is one of the most important problems relating to suspended sediment transportation. There is no doubt but that, for equilibrium conditions, there exists, for any material size, a definite relation between the amount of that material on the bed, the amount in suspension above the bed, and the hydraulic conditions at the bed. The first attempt to formalize this relation was made by E. W. Lane, M. Am. Soc. C. E., and the writer (12), and certain field data were presented indicating the existence of such a relation. Since 1939, laboratory experiments have been made which have verified this further and have indicated more definitely the parameters that enter into the relation. Experiments with very fine materials also have indicated the existence of such a relation (24). The general functional formula is as follows:

$$\frac{c_0}{c_b} = \phi\left(\frac{w}{\sqrt{\frac{\tau_0}{\rho}}}, \frac{D\sqrt{\frac{\tau_0}{\rho}}}{\nu}\right) \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

in which c_0 and c_b are the concentrations in weight per unit volume of the sediment and liquid mixture for sediment characterized by fall velocity, w, and size, D, in suspension and in the bed, respectively. Laboratory data for materials ranging in size from 0.001 mm to 0.30 mm have been obtained and these data follow the functional relationship indicated by Eq. 68.

---

[10] Associate Director, Iowa Inst. for Hydr. Research, Iowa City, Iowa.

Another item that seems to merit some consideration is the possibility of obtaining solutions to complex differential equations, such as enter into the problem considered by the author, by methods of numerical integration. The integration of Eq. 17*c*, even under simplified boundary conditions and assuming a constant value for ϵ, is a most formidable mathematical problem. Also, the final solution is so complex as to discourage its use. Methods of numerical integration have been used with success in many physical problems such as, for instance, unsteady heat flow; and, although sometimes the calculations are laborious, they are always simple and can be done by nontechnical workers.

To illustrate how numerical integration may be applied to this problem the solution to Eq. 17*c* for the two boundary conditions will be indicated. Consider a point y distance above the bottom and two points which are (Δy) above and below and which will be designated a and b, respectively. Then the values of $\frac{\partial c}{\partial y}$, $\frac{\partial^2 c}{\partial y^2}$, and $\frac{\partial c}{\partial t}$ at the point y can be written in increment form as follows:

$$\frac{\Delta c}{\Delta y} = \frac{c_a(t) - c_y(t)}{\Delta y} \quad \text{.....................} (69a)$$

$$\frac{\Delta^2 c}{\Delta y^2} = \frac{c_a(t) - 2\, c_y(t) + c_b(t)}{(\Delta y)^2} \quad \text{.................} (69b)$$

and

$$\frac{\Delta c}{\Delta t} = \frac{c_y(t + \Delta t) - c_y(t)}{\Delta t} \quad \text{..................} (69c)$$

Substituting Eq. 69 into Eq. 17*c* and letting $\Delta t = \frac{(\Delta y)^2}{2\,\epsilon}$:

$$(c_y)' = \frac{c_a + c_b}{2} + \frac{w\,\Delta y}{2\,\epsilon}(c_a - c_y) \quad \text{...............} (70)$$

in which $(c_y)'$ is the concentration at point y at a time interval Δt later than the concentrations c_a, c_b, and c_y. To use Eq. 70 the values of concentration must be known at $t = 0$ and the increment (Δy) selected; the magnitude of (Δy) to be used will be determined by the accuracy desired. In checking the curves shown in Fig. 7 the writer selected $\Delta\left(\frac{y}{h}\right) = 0.20$ which made $\Delta y = 8.32$ cm, and $\Delta t = 3.94$ sec.

Eq. 70 cannot be used for the points at the top and bottom since for these points the special boundary conditions that apply must be used when substituting into Eq. 17*c*. Thus, for the curves shown in Fig. 7, for the bottom point, $\frac{\partial c}{\partial y} = 0$. The increment equation for the bottom point then becomes:

$$(c_0)' = c_1 \quad \text{.........................} (71)$$

in which, again, $(c_0)'$ is the concentration at the bottom at $(t + \Delta t)$ and c_1 is the concentration at a point (Δy) above the bottom at time t.

For the top point, since $\frac{\Delta c}{\Delta y} = \frac{-\,w\,c_h}{\epsilon}$, the increment equation is:

$$(c_h)' = c_{h-1} - c_h\left[\frac{w\,\Delta y}{\epsilon} + \frac{w^2\,(\Delta y)^2}{2\,\epsilon^2}\right] \quad \text{..............} (72)$$

in which c_{h-1} is the concentration at a point (Δy) below the top at time t. Using Eqs. 70, 71, and 72, the values of sediment concentrations were computed for points having relative values of $\frac{y}{h}$ equal to 0, 0.2, 0.4, etc., for fourteen time increments or a total time of $14 \times 3.94 = 55.16$ sec. The values obtained checked the curve given in Fig. 7 for $t = 54$ sec as closely as this plotting could be read. For $t = 24$ sec the check was not quite as good, but adequate for practical purposes.

For the curves shown in Fig. 11, Eqs. 70 and 72 still apply; however, the bottom conditions are different since in this case $\frac{\partial c}{\partial y_0} = -\frac{w\,A}{\epsilon}$, in which A is the concentration at $y = 0$, $t = \infty$. The increment equation to use for obtaining values for the bottom point is then:

$$(c_0)' = c_1 + A\left[\frac{w\,\Delta y}{\epsilon} - \frac{(\Delta y)^2\,w^2}{2\,\epsilon^2}\right] \ldots\ldots\ldots\ldots\ldots (73)$$

in which c_1 is again the concentration at a point (Δy) above the bottom at time t. To obtain concentration values for the conditions shown in Fig. 11 the value of Δy is taken as $0.2\,h$, or 9.04 cm, and since $\Delta t = \frac{(\Delta y)^2}{2\,\epsilon}$ the values of c are obtained for time increments of 9.87 sec. Computations for twelve increments or 118.5 sec checked the values given for $t = 120$ sec in Fig. 11 fairly well. Again, the check is not as good for the first few time increments.

One of the principal advantages in solving a differential equation by numerical computation is that complex boundary conditions can be handled, and, also, in the present problem, for instance, the value of ϵ could be varied if necessary with y or t without unduly complicating the problem. Numerical methods, although inelegant and sometimes laborious, nevertheless have proved to be tremendously powerful tools in many fields of work and have provided answers to problems that could not have been solved by more formal methods.

E. R. VAN DRIEST,[11] ASSOC. M. AM. SOC. C. E.—An excellent example of the mathematical analysis of an engineering problem is presented in this paper. It clearly demonstrates the procedure followed in such a treatment; namely, the establishment of the basic assumptions, the derivation of the fundamental differential equation describing the physical phenomenon involved, the application of the boundary conditions, and the finding of a solution of the differential equation that satisfies the boundary conditions. Furthermore, the paper presents experimental data to substantiate the basic assumptions and the assigned boundary conditions.

The writer is not in full accord with the derivation of Eq. 17*b*. The assumption that $\epsilon_x \frac{\partial^2 c}{\partial x^2} = 0$ does not mean that $\frac{\partial c}{\partial x} = 0$, or that there is no diffusion of suspended matter in the x-direction. However, if it is assumed that the mean concentration is constant all along the x-axis, then there will be no diffusion in that direction; whereupon both $\frac{\partial^2 c}{\partial x^2}$ and $\frac{\partial c}{\partial x}$ will be zero and Eq. 17*b* will become, for the required steady state,

---

[11] Associate Prof., Dept. of Civ. Eng., Univ. of Connecticut, Storrs, Conn.

$$\epsilon \frac{\partial^2 c}{\partial y^2} + w \frac{\partial c}{\partial y} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (74)$$

which of course leads back to the basic Eq. 3. Eq. 17*b* is a case of steady state, but this necessitates a diffusion in the x-direction. Furthermore, the statement concerning the mathematical identity of Eq. 17*b* and Eq. 17*c* is rather difficult to follow. Certainly the solutions of these equations are independent of one another since c in the one case is a function of x and y whereas c in the other is a function of y and t. However, the statement could be interpreted so that the effect of the right-hand member of Eq. 17*b* in maintaining steady conditions is the same as the effect of the right-hand member of Eq. 17*c* in causing growth.

As a matter of generality, it can readily be shown, upon consideration of the flux of sediment into and out of a small element of volume, that the general three-dimensional equation for diffusion in a liquid stream is given by

$$\frac{\partial c}{\partial t} + U \frac{\partial c}{\partial x} + V \frac{\partial c}{\partial y} + W \frac{\partial c}{\partial z}$$

$$= \xi \frac{\partial c}{\partial x} + \eta \frac{\partial c}{\partial y} + \zeta \frac{\partial c}{\partial z} + \frac{\partial}{\partial x}\left(\epsilon_x \frac{\partial c}{\partial x}\right) + \frac{\partial}{\partial y}\left(\epsilon_y \frac{\partial c}{\partial y}\right) + \frac{\partial}{\partial z}\left(\epsilon_z \frac{\partial c}{\partial z}\right) \ldots (75)$$

in which U, V, and W are the stream velocities in the x-direction, y-direction, and z-direction and ξ, η, and ζ are the settling velocity components in the directions of $-x$, $-y$, and $-z$, respectively. Hence, it is seen that, for horizontal flow parallel to the x-axis with uniform turbulence and sediment concentration a function of y and t only, the y-axis being vertical—

$$\frac{\partial c}{\partial t} = \epsilon \frac{\partial^2 c}{\partial y^2} + \eta \frac{\partial c}{\partial y} \ldots\ldots\ldots\ldots\ldots\ldots (76)$$

Eq. 76 is the same as Eq. 17*c* when w is substituted for η. It will be noted that in the one-dimensional case the concentration is independent of the stream velocity. The fact that Eq. 75 becomes the general heat conduction equation when ξ, η, and ζ are placed equal to zero is interesting.

The author has very cleverly simplified the boundary condition at the bottom of the cylinder by requiring constant hydraulic conditions to prevail at the bed. That the pickup, in the case of run V, for such conditions is constant with time for small concentrations near the bed is probably true as can be inferred from the physical picture, but the pickup would undoubtedly change for larger concentrations near the bed because of the effect of the sediment on the turbulence mixing and the mutual interference of the solid particles. It seems that this action should be somewhat analogous to that of the transfer of heat from a wall of fixed temperature to a turbulent fluid; here the eddies coming in contact with the wall carry away heat at a rate depending upon the mean temperature of the eddies near the wall. The fact that the experimental data agree closely with the theoretical curves proves the author's choice of this bottom condition to be valid.

The author should be commended for his perseverance and ingenuity in accomplishing the theoretical analysis and performing the experimental work.

R. SCHUHMANN, JR.,[12] ESQ.—The treatment of the effect of turbulence on sedimentation, presented in this paper, will be of widespread general value because, both experimentally and theoretically, the simplest possible turbulent-sedimentation system was considered. That is, the particles were in a dispersed state and of one size and one settling velocity; the suspensions were dilute; agitation was uniform with respect to depth; and there were no horizontal currents. Because of the complicating effects of variable particle size, flocculation, concentrated suspensions, variable turbulence, etc., only empirical data can be obtained in practicable sedimentation systems.

The sedimentation systems with which the writer is familiar occur in separation operations for dressing minerals. These operations pertain not only to the separation of suspended matter from fluids but also to the grading of particles according to size, and to the separation of particles of one mineral from those of another when the minerals differ in specific gravity. Turbulence, induced both by flow and by mechanical agitation, undoubtedly plays a large rôle in some of these operations, and Ensign Dobbins' methods seem to afford a good starting point for fundamental study.

The writer is particularly interested in the observations on pickup, since various devices for separating minerals require maintaining conditions of selective pickup at the bottom of a stream. Gold, cassiterite, and other heavy minerals are separated from quartz and other light gangue minerals in this way. In some respects the "rheolaveur-launder" process for separating coal and slate is also of the same nature.

H. B. SOUTHWOOD,[13] ESQ.—Although limited in scope by the necessity for simplification in order to arrive at equations possible of solution, the author's study provides additional verification and extension of principles forming the basis for the largely qualitative analyses on which the engineer must often depend when he deals with problems of open-channel flow involving sediment transportation and deposition. The definition of any of the factors relating to these phenomena, however circumscribed may be the conditions under which the analysis is made, is a step forward and eliminates at least some part of the guesswork included in the process generally termed "engineering judgment" or "engineering intuition." The author's rational approach, resulting in an expression of the relations between such factors as concentration at any point, pickup, hydraulic conditions at the bed, and characteristics of the bed material, certainly constitutes such a forward step. Direct application of the results to the solution of practical problems must necessarily await the formulation of methods whereby turbulence can be classified, evaluated, and measured. Further investigations of turbulent suspensions may result in the establishment of relations that will permit the measurement of turbulence by means of sediment observations. The development of a relatively simple field technique based on such relations would be an invaluable tool in the study of natural streams and other open channels.

---

[12] Asst. Prof., Mineral Dressing, Dept. of Metallurgy, Mass. Inst. Tech., Cambridge, Mass.

[13] Chf., Hydr. Section, Dept. of Public Works, State of Louisiana, Baton Rouge, La.

Regarding the observed lack of conformity between experimental data and theoretical values as plotted in Fig. 7, the two factors mentioned by the author (upward transportation of material when the cylinder was dropped, and pickup of the material lodging on the grid surface) are considered to have had the described effects. However, at least two additional factors are believed to have contributed to the existence of observed concentrations in excess of plotted theoretical values.

(1) The use of an arithmetical average value for settling velocity in the computations may result in erroneous positions of the theoretical curves. A range in values of from 0.150 cm per sec to 0.344 cm per sec appears rather wide. Analyses of individual samples obtained during the course of the run probably would have given some insight into the effect of this factor.

(2) The method of sampling is subject to errors which may be sufficiently great to account for most of the deviation noted in Fig. 7. The description of sampling procedure indicates that flow through the siphon was in progress for 12 sec to 18 sec prior to beginning of collection of each sample. This should be a sufficient period for the establishment of a field or zone of undetermined lateral and vertical extent in which the pattern of turbulence would be distinctly altered by the velocities of the converging flow entering the siphon tube. Since these sustained velocities undoubtedly had substantial upward components throughout the major portion of the affected field, it follows that concentrations of suspended material entering the sampling tube would be in excess of those existing at the same elevation in other portions of the container.

L. Standish Hall,[14] M. Am. Soc. C. E.—Although the tests and theory described in this paper are primarily intended for application in the design of settling basins, the author indicates that the same principles may be used for studies of sediment load in natural streams. A modification of the formulas would be required before such a general application could be made. The author states that "the simplifying assumptions involved in Eqs. 17 may introduce large errors when applied to the case of a natural stream." This is undoubtedly true.

The settling rate of suspended particles conforms with Stokes' law (25). The lucite used by Ensign Dobbins in the experiments had a specific gravity of 1.194 as compared with a specific gravity of 2.65 for normal stream sediment. The diameter of the lucite particles ranges from 0.138 mm to 0.216 mm. By Stokes' law, these diameters would correspond to diameters of 0.048 mm to 0.075 mm for stream sediment of the usual specific gravity.

Suspended sediment in stream channels normally is composed predominantly of silty loam with some percentage of clay and some percentage of fine sand. Medium or coarse sand, gravel, and boulders ordinarily move on the stream bottom as bed load. The analysis of suspended-stream sediment indicates that normally 70% to 80% is of a smaller diameter than the equivalent of the lucite; also, that from 10% to 20% is of larger diameter. Therefore, the tests are indicative of the performance of larger sizes of suspended sediment in streams.

---

[14] Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

In the transportation of sediment in stream channels, the movement of the bed load absorbs a part of the momentum. This action undoubtedly influences the relation between the suspended load and the total load, so that the latter depends on the relative quantity of each type of load carried in the stream channel. Without some such explanation, it is difficult to interpret the results of actual measurements of silt load. For example, the maximum concentration of sediment usually occurs prior to the peak discharge; and the sediment load carried by a stream varies between a rising and a falling stage, being greater in the former, and also varies with the same discharge between different storms (26).

More study is required on the larger problem of the distribution of sediment particles in a natural stream channel because of the greater number of variables that must be introduced. Notwithstanding the limitations of the formulas, Ensign Dobbins' paper is a valuable contribution to the theory of sedimentation.

WILLIAM E. DOBBINS,[15] JUN. AM. SOC. C. E.—Many interesting and important suggestions have been revealed in the discussions of this paper. The ultimate solution to this difficult problem is still to be found. The principal difficulties lie in obtaining the solution to the general form of the differential equation and in finding the complete relationship between the rate of pickup from the bottom and the factors that control it. Professor Kalinske has reported progress on the latter problem.

If these difficulties can be overcome, the resulting equations undoubtedly will be very cumbersome. However, it is much better to introduce simplifications after the correct solution has been found than before. Long and tedious calculations need be made only once since the results can be preserved in the form of tables or charts. The writer hopes that he may have contributed some ideas that will help others who are working on this and other related problems.

THE QUEENS MIDTOWN TUNNEL

By Ole Singstad,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Thomas W. Fluhr, Howard L. King, Francis V. Wagner, William J. Wilgus, S. A. Thoresen, H. G. Cruthers, Leo Geenens, Charles E. Conover, Edward Levy, Robert F. Legge, Orrin L. Brodie, A. A. Eremin, Arthur S. Tuttle, and Ole Singstadt

Synopsis

The engineering features of the Queens Midtown Tunnel, including its function from the standpoint of automotive transportation, its planning, design and construction, are discussed. An attempt has been made, within the permissible limits of space, to emphasize certain features of the project which presented more than the usual problems.

Introduction

The Queens Midtown Tunnel is a subaqueous highway crossing of the East River in New York, N. Y. It extends in an east-west direction between the

east side of the midtown section of the Borough of Manhattan and Long Island City in the Borough of Queens. Its location, highway connections, and relation to the New York City metropolitan area are shown in Fig. 1, which is based on the present (1943) status of development of highways and parkways. The tunnel exits and entrances in Manhattan connect with the local street system and are conveniently situated with respect to the East River Drive, which extends along the east shore of Manhattan Island. In Queens, the principal connection to the tunnel is the Midtown Highway which, via the Connecting Highway, provides an express route to Queens Boulevard, the main central traffic artery of Queens. The latter, in turn, leads to and from the express parkway and highway system of Long Island. The Queens plaza also provides connections via 21st Street (Van Alst Avenue), 50th Avenue, and Borden Avenue to the local street system and areas in Brooklyn and Queens directly tributary to the tunnel.

Fig. 2.—General

Fig. 2 shows the general plan and profile of the tunnel. Between portals, the tunnel structure includes two cast-iron-lined shield-driven tubes, 31 ft in diameter, 3,760 ft long, two structural steel-lined tubes in rock tunnel, 32 ft 10 in. in diameter, 1,051 ft long, and steel bent and concrete structure for a length of 387 ft in Manhattan and 1,051 ft in Queens. In all essential respects, the design of the tubes, interior details, and provisions for ventilation and lighting are of the same design as for the Holland Tunnel and the other modern tunnels for automotive traffic that have been designed and constructed according to the Holland Tunnel pattern. (The Holland Tunnel was built by the New York State Bridge and Tunnel Commission and New Jersey Interstate Bridge and Tunnel Commission under the Hudson River between Canal Street and Broome Street, Manhattan, and 12th Street and 14th Street, Jersey City, N. J. It was opened to traffic November 13, 1927.) The tubes have an interior lining of concrete with walls and ceilings finished in tile. The roadways, which are paved with brick, are 21 ft wide between curbs, increased to a maximum of 23.5 ft on curves, providing for two lanes of westbound traffic in the north tube and two lanes of eastbound traffic in the south tube. The roadway headroom is 13.5 ft.

Plan and Profile

The tunnel plazas, paved with brick in areas adjacent to the portals and with concrete beyond those areas, widen from the two lanes at the portals to six lanes for each direction of travel. Ventilation equipment is housed in two buildings, one on each side of the river. Remote control of ventilation and lighting, offices for the supervisory staff, quarters for maintenance crew and tunnel police and equipment are provided for in the service building in Queens. A garage for the emergency wrecking tractors is located at each plaza. Booths (ten single and one double) for the collection of tolls in both directions of travel are situated on the Queens plaza, approximately 432 ft from the tunnel portals.

General data describing the tunnel are as follows:

Traffic.—Estimated maximum capacity, in vehicles per year	16,000,000
Dimensions.—Length of crossing between plazas, in feet (from street grade to street grade)—	
Westbound	7,865
Eastbound	7,400
Maximum Grades Between Portals (%).—	
Up	3.5
Down	4.0
Maximum Grades at the Plazas (%).—

Grant in aid	$11,235,000.00
Forty-year loan, at 4%	$47,130,000.00

HISTORICAL

A preliminary plan for a tunnel between Long Island and mid-Manhattan, extending across town to the west side, was first officially prepared by the president of the Borough of Manhattan in January, 1926. The idea of such a tunnel was endorsed early in the same year by the Regional Plan Association, Inc. (then the Committee on the Regional Plan of New York and Its Environs). In 1923 this committee had included in its scheme for main highway routes in the New York district[2] an east and west traffic axis from Long Island to New Jersey across midtown Manhattan. This plan contemplated the use of the

---

[2] "Highway Traffic," *Regional Survey of New York and Its Environs*, Vol. III, p. 29.

Queensborough Bridge as the East River link in the route; but it was proposed that two new tunnels across the Hudson River be located between 59th Street and the Holland Tunnel, which was then being constructed.

From 1926 to 1935, the 38th Street-East River Tunnel (as it was first designated) was strongly advocated by many interested civic and business associations and groups as a means of:

(*a*) Relieving traffic congestion on existing East River bridges, particularly the Queensborough Bridge;

(*b*) Providing a necessary modern express link for vehicular traffic joining Manhattan Island with the rapidly growing Borough of Queens, the Borough of Brooklyn, and the highway system of Long Island; and

(*c*) Stabilizing the midtown Manhattan area as a center for business, manufacturing, shopping, amusements, hotels, and residence.

The Department of Plant and Structures of the City of New York made preliminary engineering studies and rendered a report on the project in June, 1929. In July of the same year, the Board of Transportation was assigned the work of preparing plans and specifications and starting construction with an initial appropriation of $2,000,000. The financial depression following the stock market crash of 1929 resulted in the rescinding of the greater part of this appropriation and the suspension of work on the project in 1931, at which time a plan for the East River crossing had been formulated.

The act of the New York State Legislature creating the New York City Tunnel Authority set up the East River crossing of the original project as separate from the east-west crossing of Manhattan Island; and in January, 1936, the Public Works Administration (PWA) allocated $58,365,000 for the construction of the East River crossing, or Queens Midtown Tunnel, with the understanding that the city would construct an express connection from the tunnel plaza in Queens to the main highway system of Long Island, to be completed by the time the tunnel was opened to traffic. The first work of the Tunnel Authority was a restudy of the tunnel plan and the development and adoption of the plan shown in Fig. 2. Ground was broken for the project on October 2, 1936, by President Franklin D. Roosevelt, and, after a construction period of slightly more than four years, regular operation of the tunnel was started on November 15, 1940.

TUNNEL HIGHWAYS, CONNECTIONS AND TRAFFIC

In conformity with the promise made by the city at the time the tunnel project was financed, the scheme of connections and highways in Queens contemplated the completion, simultaneously with that of the tunnel, of the extension of Midtown Highway as far east as the junction of Horace Harding Boulevard, Queens Boulevard, and Woodhaven Boulevard. Although the construction of this extension of the Midtown Highway has been deferred temporarily, its necessity is apparent, as the existing alternate route via Connecting Highway and Queens Boulevard has insufficient capacity to provide for the normal growth of local, tunnel, and other interborough traffic using it, and is, in other respects, unsuitable and inadequate as part of the main east-west route of the tunnel.

In Manhattan, where the congestion which now exists on the crosstown streets of the midtown area west of Third Avenue and east of Eighth Avenue is a serious impediment to vehicular travel, the proposed Midtown Manhattan Underpass will provide an express route between the Manhattan plazas of the Queens Midtown Tunnel, the West Side Express Highway, and the Lincoln Tunnel. Its construction, with that of the highway improvements planned in Queens, is necessary to complete the express highway system joining Long Island, Manhattan, and New Jersey by a route through the center of the metropolitan area, of which the Queens Midtown Tunnel is a part.

The Queens Midtown Tunnel is the seventh East River crossing for vehicular traffic to be constructed and the first tunnel crossing of the East River for automotive vehicles. Vehicular traffic crossing the East River had increased twentyfold from 4,500,000 trips per annum in 1910 to 90,000,000 trips per annum in 1936. The Queensborough Bridge, which is the most heavily traveled of these crossings, increased in vehicular traffic from 769,000 trips in 1910 to a maximum of 36,000,000 in 1933, a toll-free volume approximately equal to that of all the Hudson River crossings from the Battery to Tarrytown. The Queens Midtown Tunnel, charging a base toll of 25¢ for passenger cars and light trucks, functions principally as an express alternate to relieve this load.

Maximum peak hour traffic recorded for the tunnel to date (March, 1943) occurred on Wednesday, December 24, 1941, between 8 a.m. and 9 a.m., when 2,075 cars used the westbound tube. This peak was easily handled with five of the toll booths on the Queens plaza, and smooth flow of traffic through the tunnel was maintained, giving a practical demonstration of the adequacy of entrance and exit plazas and approaches.

Tunnel Plan

The East River crossing, or the present plan of the Queens Midtown Tunnel, was authorized for construction in 1935, after careful consideration had been given to prior plans such as those of the president of the Borough of Manhattan (1926) and the Board of Transportation (1931). The Lincoln Tunnel under the Hudson River was already being built. Every one who had investigated these projects from the first inception had agreed that the East River and Hudson River crossings should be located so that an under-Manhattan connection could be conveniently provided. Therefore very little choice was possible in the location of the Queens Midtown Tunnel. The location was further limited by the Pennsylvania Railroad tunnels at 33d Street and by the Steinway Tunnel at 42d Street.

That this location was the correct one for both the Hudson and East River tunnels was established by traffic surveys made on both rivers showing that the midtown section was the one which was most urgently in need of traffic relief on both rivers; and, although the general location of the Queens Midtown Tunnel was established by legislative enactment, there was real justification for such location. The East River crossing received intensive study by the

Tunnel Authority, and a great many study layouts were made before the final plan was adopted. All of the earlier plans developed by other city departments showed approach plans for the tunnel on the Manhattan side which were deemed unsatisfactory from the point of view of the free and expeditious handling of traffic without congestion.

Conditions affecting the choice of plaza and approach locations in Manhattan included the character of the topography, real estate costs, and street and tunnel traffic considerations. These conditions limited practical locations of the Manhattan plazas to the area south of 40th Street between Third Avenue and the East River where the ground surface is comparatively flat and low in elevation, where values of real estate were generally within allowable limits, and where traffic on crosstown streets is not heavy. West of Third Avenue the street grades rise more rapidly into the Murray Hill section of Manhattan, increasing, in some instances, to a rate of almost 7%. The high value of real estate in certain blocks eliminated these from consideration as possible sites for the plazas, and, in general, the values of real estate increase, as the center of the midtown section is approached, to prohibitive sums in so far as the allowable costs of the tunnel project were concerned. Local traffic on the crosstown streets east of Third Avenue is comparatively light, whereas, if the tunnel plazas were built farther west, the great increase in volume of traffic would seriously affect the convenience of travel.

The War Department required certain minimum depths of channel and tunnel structure between U. S. pierhead lines, the prescribed minimum depth of the top of the tunnel tubes at the Manhattan pierhead lines being 48 ft below mean low water with a minimum depth of channel of 38 ft below mean low water. To provide a minimum cover of 13 ft over the tubes, the depth of the structure at the pierhead line was actually fixed at 51 ft below mean low water. The crown of the tunnel roadway is 21.77 ft below top of tube. It would have been impossible to reach street grade at the desired points with direct alinement from the depth of roadway so fixed at the pierhead line and stay within maximum permissible tunnel grades. Accordingly, a plan was adopted in which the line of the East River crossing from Borden Avenue, in Queens, extends to a point at the Manhattan pierhead line between the lines of 41st Street and 42d Street extended, the necessary distance being developed along First Avenue to the plaza locations between 36th Street and 37th Street. This crossing of the river is no greater in length between pierhead lines than the direct one.

The entrance and exit plazas in Manhattan are separated so as to avoid concentrating tunnel traffic in too small an area, and to avoid conflict between traffic bound for the tunnel and that from it. Wider separation was not practicable, as moving the exit plaza north would have resulted in steeper grades and greater real estate costs, whereas restriction on the use of park property prevented moving the entrance plaza farther south. The exit plaza passes under Second Avenue above the level of the proposed Second Avenue subway; it is bridged between First Avenue and Second Avenue to permit tunnel-bound traffic to reach the entrance plaza from points north of 37th Street.

The surface approaches are three lanes wide, those for exit extend between Second Avenue and Third Avenue connecting with all crosstown streets from 34th Street to 41st Street, inclusive, with the exception of 36th Street, where there is an underpass for southbound tunnel traffic to prevent conflict with traffic on 36th Street bound for the tunnel. The entrance approaches extend between First Avenue and Second Avenue and connect with all crosstown streets between 34th Street and 40th Street, inclusive. By this scheme of surface approaches connecting with the plazas, tunnel traffic is not concentrated on any one crosstown street, and does not conflict with the traffic on the heavily traveled north and south avenues.

The Manhattan plazas and approaches of the tunnel are so designed as to permit the construction, at any time in the future, of plazas and approaches for the Midtown Manhattan Underpass, with provision for direct connections between the underpass and the tunnel.

In Queens, real estate values were relatively low and the slope of the terrain was very gradual east from the river, reaching an elevation of 15 ft above mean high water at Borden Avenue and 21st Street.

Under these favorable conditions, the most advantageous location for the plaza was found north of Borden Avenue and east of Vernon Boulevard and Jackson Avenue (see Fig. 2), where connections to Midtown Highway and 21st Street (Van Alst Avenue) were conveniently made.

At the U. S. pierhead line on the Queens side, the War Department prescribed that, with due consideration for the thickness of permanent protective covering decided necessary, the depth of top of tubes below mean low water should be a minimum of 43 ft. Street level at the plaza was easily reached with suitable grades from a depth at the pierhead line 5 ft greater than the prescribed minimum. The lowering of the tunnel profile below the minimum by this amount provided additional thickness of rock cover in the full rock sections and permitted a greater length of tunnel to be excavated entirely in rock.

The results of studies for the location of ventilation shafts and buildings on either side of the East River placed the shaft and building in Queens in Borden Avenue about 50 ft east of Front Street and, in Manhattan, about 250 ft east of First Avenue between 41st Street and 42d Street. This original location of the Queens shaft contemplated the caisson method for its construction. When bids were received for this work, which was included in the contract for the river tunnels, it was found that a substantial saving could be effected by moving the shaft about 200 ft farther east where it could be constructed in the open-cut section, and, by agreement with the contractor, this change of location and design was made.

The low point of the tunnel is approximately 1,168 ft east of the Manhattan ventilation shaft in the rock reef near the middle of the East River, making it possible to construct the midriver sump and pump chamber entirely in rock between tubes.

On the line of the river crossing of the tunnels, the west channel of the East River reaches a depth of 66 ft below mean high water. This depth would have required lowering the tunnel profile considerably to maintain a suitable cover over the tunnel, thus increasing the air pressures necessary for construction. Furthermore, as this channel depth occurred near the Manhattan pierhead line, it would have increased the length of line necessary to reach the surface in Manhattan. The profile of the tubes at this point was made high enough to avoid these conditions, and for approximately 150 ft in each tube, the top is above the original bed of the river (maximum 8 ft). The War Department permit included provision for a permanent blanket of clay overlain with a protective layer of riprap of sufficient extent and depth to maintain a minimum cover of 13 ft over the tubes in this area.

Geologic Data

Test borings were made at the plaza and approach sites and along the line of the tunnels to determine the topography of the rock floor, the character and kind of rock and overburden, and, in the land areas, ground-water elevations. When rock was encountered, a core was taken of sufficient length to establish the material as ledge rock, generally a minimum of 10 ft.

Borings along the river crossing were staggered north and south of the tube locations and were generally not farther apart than 200 ft measured along the line of the tunnels. They were taken closer together where necessary, to develop the contour of the rock surface.

The rock floor was disclosed to be exceedingly irregular in both elevation and character, consisting of Manhattan schist under Manhattan and changing progressively to Inwood limestone, Fordham gneiss, Hell Gate dolomite, and Brooklyn injection gneiss along the tunnel line to Queens. There were zones of disintegrated rock lying at low points, generally at the contacts of one formation with another. The overburden was indicated to be mostly pervious glacial deposits consisting of sand, gravel, and numerous boulders. The face of tunnel excavation was shown to pass many times in and out of full rock, mixed ground, and soft ground.

Design of Structures

Lining for Shield-Driven River Tunnels.—Cast-iron lining of the usual design was chosen for the shield-driven tunnels as best adapted to resist shield thrusts and to provide rigidity and watertightness. The length of straight ring was 32 in., or 2 in. greater than the maximum length of ring heretofore used in the river tunnels around New York City. This longer ring was used with complete success and resulted in a saving of material and erection costs and in faster progress as compared with shorter ring lengths. A width greater than 32 in. was impracticable at the time because of foundry limitations; 1¼-in. and 2½-in. taper rings, used to provide for vertical and horizontal curvature and corrections to alinement and grade, were a maximum of 32 in. in length.

Each ring was made up of fourteen segments and a key, and two weights of cast-iron lining were used. The heavier ring, as shown in Fig. 3, with 14-in. flanges and weighing approximately 22.7 tons per ring, was used in soft ground and mixed face or where the character or thickness of rock cover required it; the lighter ring with 11-in. flanges and weighing approximately 12.5 tons was used in rock face where the cover was adequate.

The segments making up the tunnel ring were bolted together with four high-strength steel bolts in each cross flange, and adjacent rings were bolted together with eighty-five high-strength steel bolts in the circumferential flange, the bolts for the heavy rings being 1¾ in. in diameter and those for the light rings, 1⅝ in. in diameter. The specified yield point for the bolts was 85,000 lb per sq in., and the ultimate strength was 110,000 lb per sq in.

Fig. 3.—Heavy Cast-Iron Tunnel Lining Details

The load factors which were used in designing the heavy cast-iron lining are the weight of the cast-iron ring and that of the concrete lining; the full weight of earth and water above the horizontal diameter of the tunnel; lateral earth and water pressures; and the effect of buoyancy. The load factors used in designing the light cast-iron lining were the weight of the cast-iron and concrete linings, full hydrostatic pressure, and a load of 10 ft of rock packing above the top of the tunnel. The ring as thus designed was investigated for localized grout pressures.

The strength and efficiency of the segmental cast-iron ring depend on the capability of the bolts in the cross flanges to transmit the tunnel ring stresses between segments; and, with the cross joints of adjacent rings staggered, the bolts in the circumferential flanges connecting the adjacent rings, with proper bolt tightening, add materially to the strength of the cross joints by the splicing action provided.

An initial tension in the bolts of 25,000 lb per sq in. was specified. The bolts, which were erected with steel washers and hemp rope grommets, were tightened by hand, generally by two to three men on a ratchet wrench. A 5-ft wrench was used for the heavy cast-iron lining and a 4-ft wrench for the light lining. Actual bolt stresses, observed some time after the tunnel lining was erected, varied from intensities considerably less than 25,000 lb per sq in. to stresses approaching the yield point of the bolts. It is now considered good practice to make an allowance of about 5,000 lb per sq in. above the required bolt stress to offset any plastic yield effect in the entire bolt assembly under sustained loading.

Initial bolt stresses that are too low, and lack of uniformity in stress, may contribute to some leakage, especially in the case of the light cast-iron lining, as the flanges are thinner and more flexible than those of the heavy cast-iron lining and the surrounding material has no tendency to silt up any small crevices that may exist between flanges. Since even very small leaks may be objectionable as affecting the appearance of the tile-finished interior of a modern vehicular tunnel, it would be desirable to use machine tightening for the bolts in the light cast-iron lining. As a further safeguard against leakage, the light cast-iron lining may be designed with five bolts in the cross flanges. The fifth or center bolt of each cross flange has been omitted in recent tunnel design as theoretically carrying no stress.

The outside faces of all flanges of the Queens Midtown Tunnel lining were machined according to standard practice. The specified tolerance on the width of ring segments was very small (0 to $-\frac{1}{64}$ in.), in order to secure as tight a fit as possible along circumferential flanges. The lining was calked for watertightness with lead wire in the grooves formed at the inner edges of the flanges, the calking rebate on each segment being specified to have a maximum depth of $\frac{3}{16}$ in. so that a calking groove would be a maximum of $\frac{3}{8}$ in. in width when two segments were joined. Heavy machining on flange faces sometimes narrowed this groove so as to make calking difficult.

Permanent tunnel tie rods at ceiling and roadway levels were placed in the Queens Midtown Tunnel lining for short distances in both tubes under the Manhattan bulkhead area, where there might be changes in outside loadings after the tunnel was built which would possibly cause variations in the stresses in the lining. Permanent tunnel tie rods were also placed at the midriver sump, where certain segments of the tunnel lining were not erected because of the construction of the cross passage between tubes.

Midriver Sump and Pump Chamber.—The midriver sump and pump chamber are between the tunnels and consist essentially of two tubes, each one composed of segmented cast-iron rings with an interior lining of concrete. The axis of the pump chamber is at right angles to the main tunnels. The pump chamber rings are 16 ft in outside diameter, giving sufficient inside space, in addition to that required by the pumps, for a pedestrian cross passage between the main tunnels. The sump is 42 ft long, out to out, with rings of 14-ft outside diameter, and is located below the pump chamber with its axis parallel to, below and about midway between, the main tunnels. The pump chamber and cross passage are connected to the main tunnels by short rectangular structural steel frames and plates.

Rock Tunnels and Steel Bent and Concrete Structure, Manhattan.—In order to provide for the roadway widths which, because of the curved alinement, are increased to 23.5 ft in Manhattan, the metal lining, in the length of the rock tunnel sections extending from east of the Manhattan ventilation shaft to 38th Street, is designed with an outside diameter of 32 ft 10 in. These rock sections of tunnel were constructed as far as 41st Street under the contract for the river tunnels. Another contract was let for the structure from 41st Street to the tunnel portals, located just west of First Avenue between 36th Street and 37th Street, consisting of a continuation of the metal-lined rock tubes to 38th Street and steel bent and concrete structure from 38th Street to the portals. All of the metal lining, 32 ft 10 in. in diameter, was furnished under this contract, three alternative designs being submitted to the contractors for competitive bidding.

The three designs were based on the same strength factors, namely: To resist full hydrostatic pressure, plus a crown load of 10 ft of broken stone and grout estimated to amount to 1,500 lb per sq ft. One alternative was a lining 32 ft 10 in. in diameter, constructed of light cast-iron rings 32 in. long. The other two alternatives were linings of structural steel, designated as type 1 and type 2. Both type 1 and type 2 were rings of ten segments 5 ft in width and about 113 in. long and a key segment about 16 in. long. The weights of the two types were each about 2.2 tons per linear foot of tunnel. Type 1 was made of skin plates welded to circumferential and segmental flange plates 5¼ in. deep. The bulk of the stiffness and circumferential strength of the ring was provided by two split I-beams placed at the quarter points of the ring, bent to the tunnel radius, welded, and spliced with bolted connection plates at each cross joint to form a continuous circular rib. Type 2 also had segmental flange plates welded to the skin plate at each end, but the skin plate was bent to form circumferential flanges 9½ in. deep. One split I-beam ring was provided instead of two as on type 1.

Upon receipt of competitive bids, structural steel type 2 was found to be the least expensive of the three alternatives, and the contract was let on that basis. A third design in structural steel was submitted by the contractor (see Fig. 4). This design, which presented a saving in cost to the Tunnel Authority, differed from type 2 in that specially rolled bulb angles were provided for the circumferential flanges instead of bending up the skin plates. It was approved and installed.

The steel bent and concrete structure in Manhattan (Fig. 5(*a*)) extends from the circular tunnels, where the junction is made by bellmouths around the tubes, southwest to the plaza portals. The type of construction consists of structural steel bents spaced about 5 ft on centers down to the roadway level, below which the fresh air duct is of inverted reinforced concrete arch construction. Since the invert is in rock for its full length, this construction was found to be the most economical.

There is very little regularity to the steel bent and concrete structure in Manhattan. As the grade ascends to go into the plaza, the earth cover diminishes making it necessary to bring the exhaust air ducts from the top to one side of the structure. Special construction was necessary to form the junction between the circular tunnels and the rectangular section and also at the portals, where the structure is belled out to provide a gradual transition from tunnel lighting to daylight. Where the west tunnel passes under private property in the block between 38th Street and 37th Street, the structure was designed to support future 12-story storage warehouse buildings with floor live loads of 200 lb per sq ft.

Steel Bent and Concrete Structure, Queens.—The Queens land section was constructed entirely in trench from the construction shaft to the Queens plaza portal, a distance of 1,051 ft. For about one half of this length the structures for eastbound and westbound roadways were separated with a berm of earth and rock, and, for the remaining length, a single structure carries both roadways. The structural type is a steel bent spaced about 5 ft on centers, embedded in concrete and waterproofed with fabric and brick in asphalt mastic (see Fig. 5(*b*)).

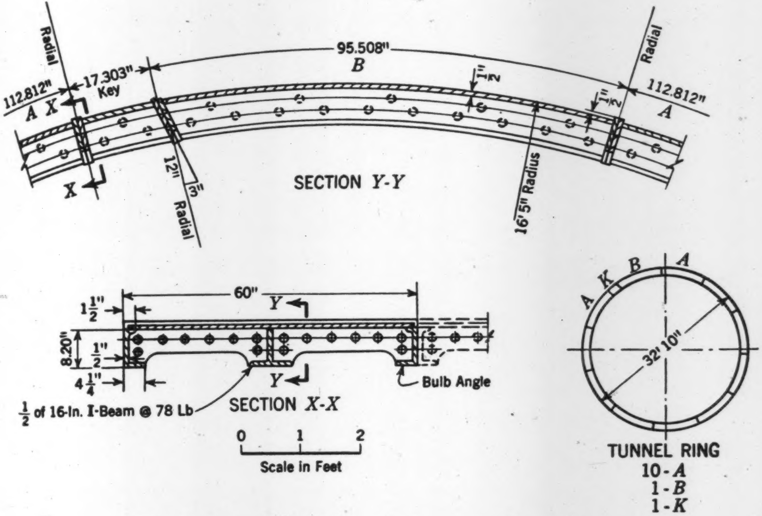

Fig. 4.—Steel Lining Details Designed for Use in Rock

The extreme west end of this land portion serves as the foundation for the Queens ventilation building, and provision was made in its design for all of the features normally located in a ventilation shaft—air ducts, emergency stairs, elevator, drainage sump, pump chamber, cable splicing chambers, etc.

This foundation structure was brought up to an elevation about 3 ft above the street surface and was designed to form the first floor of the ventilation building. Five pairs of steel girders, 5 ft in depth, distribute the building column loadings to the tunnel structure below and to ten circular steel-shell concrete-filled piers, varying from 4 ft to 4.5 ft in diameter, five located on each side of the tunnel structure and extended down to rock.

The depth of the structure made it possible to effect a substantial economy by placing the fresh air ducts above the ceiling for a large portion of the section instead of in the normal position below the floor. Toward the portal end of the section, the shallow depth of cover over the structure entailed the transition of

both the fresh air ducts and the exhaust ducts from above the ceiling to a location between the tubes.

Tunnel Interior.—The interior features of each tube include: (1) An interior concrete lining in the metal-lined sections of the structure; (2) roadway slab and paving; (3) a walk on the left of the direction of travel, approximately 2 ft 8 in. wide and 3 ft 6 in. above paving level; (4) a fresh air duct generally under the roadway, connected to the roadway space by fresh air flues; and (5) an exhaust air duct, generally above the ceiling, connected to the roadway space by openings in the ceiling. Fig. 6 shows a typical tunnel section.

The roadway slab consists of transverse 10-in. I-beams spaced 21 in. on centers with longitudinal reinforcing rods above and below, and transverse reinforcing bars between the I-beams. The roadway slab is designed in accordance with the theory advanced by H. M. Westergaard,[3] M. Am. Soc. C. E., in 1930. The roadway beams rest on concrete benches and when placed over fresh air flues are supported on 8-in. I-beams which span the flues. The ceiling slab, containing the exhaust ports, is a reinforced concrete slab 5.5 in. thick supported at the sides of the tunnel and hung at the center by stainless steel bars generally 10 ft 8 in. apart.

---

[3] "Computation of Stresses in Bridge Slabs Due to Wheel Loads," by H. M. Westergaard, *Public Roads*, 1930, Vol. 11, No. 1. pp. 1–23.

The fresh air flues are not terminated in a continuous expansion chamber, as has been the practice heretofore, but discharge directly into the roadway space through openings 5 ft 4 in. long and 3 in. wide, formed in the glazed architectural terra-cotta blocks at the front of the benches (see Fig. 7). Experience has shown that the distribution of fresh air along the roadway can be just as efficient and continuous with direct discharge into the roadway space as through a continuous expansion chamber, particularly when the fresh air flues on either side of the roadway are staggered, and when the movement of traffic furnishes longitudinal distribution.

Clay ducts under the sidewalk are used for low-tension cables as, from this location, wiring to control boxes for signals, telephones, etc., was simpler than if low-tension conduits were placed in the opposite wall as has been the previous practice. Continuous lighting-cable conduits are placed in the walls of the upper air duct so that no conduits of any kind are contained in the ceiling slab.

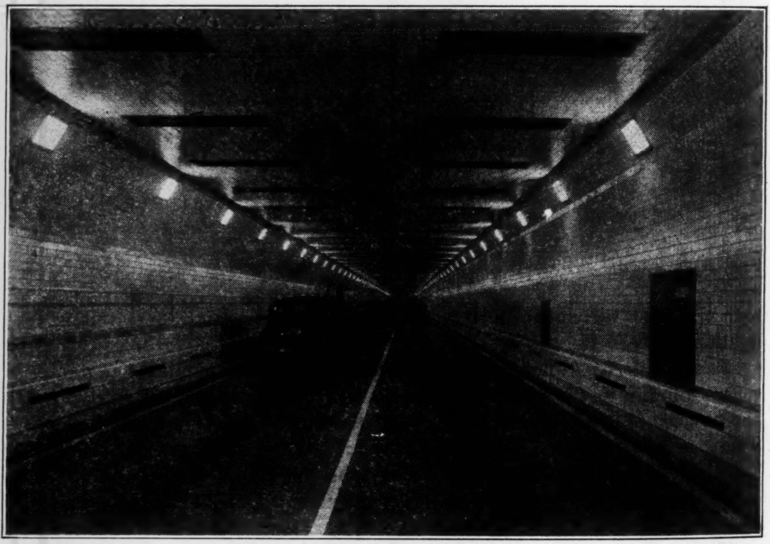

FIG. 7.—FINISHED INTERIOR OF TUNNEL

In each tunnel, between ventilation buildings, six 4-in. asbestos-cement conduits are provided in the wall opposite the sidewalk. The lower three conduits are so spaced as to be suitable for high-voltage transmission cables, and the upper three conduits are suitable for lower-voltage cables. The six conduits are available for rental, and are carried up the shafts to street-level splicing chambers in each ventilation building, where connections may be made to private transmission lines entirely independent of tunnel services.

Low-tension splicing chambers in the sidewalk bear a more or less constant relation to the police posts, which house the telephones and manual signal controls. These posts are spaced at such intervals as to provide visibility and easy access to the portions of the tunnel between them, in general about 250 ft. Two small niches, each holding one 15-lb carbon-dioxide fire extinguisher, are in the wall above the sidewalk at each control station and two additional small fire extinguisher niches are installed midway between control stations. This spacing makes fire extinguishers readily available to the tunnel policeman on duty at the control station. Larger fire extinguisher niches, each niche containing three 15-lb carbon-dioxide fire extinguishers, are installed in the wall on the side opposite the sidewalk. These niches are spaced at approximately 250-ft intervals for use by the tunnel police or by others. Niches containing 100 ft of racked fire hose attached to a $2\frac{1}{2}$-in. valved outlet from the 6-in. tunnel water service pipe are spaced about 125 ft apart. The chemical fire fighting equipment distributed through the tunnel (aggregating 350, 15-lb carbon-dioxide fire extinguishers) is ample for all small fires and is sufficient for the control of larger fires until such time as the emergency wrecking tractor and the police car (each of which is equipped with a foam generator type of fire extinguisher), which answer all fire calls, can arrive on the scene.

Other niches in the tunnel are:

Niches	Spacing (in feet)
Tools	500
Gate valve and clean-out for shutting off and cleaning out the 6-in. water service line	500±
Access to valves controlling outlets from the 6-in. water service pipe to the fresh air duct to flush the latter	500±
High-tension splicing chambers	460±

Roadway and ceiling manholes are spaced about 500 ft apart.

The tunnel roadway is paved with de-aired vertical fiber brick $3\frac{1}{2}$ in. in depth, laid transversely on a $\frac{3}{4}$-in. bituminous mastic cushion. Joints between bricks are filled with pure asphalt with 20% to 30% inert fine material added. The center line marker—a single continuous line on tangent and slight curves, and two continuous white lines about 8 in. apart on the sharper curves—is made with pure white-body vitreous bricks with hard bright, white glazed top surfaces and laid longitudinally end to end. Wherever double-lane markers are used, electrically illuminated amber prisms, protected by cast-steel hoods, are installed in the paving between the lanes at regular intervals.

The roadway surface is crowned 1 in. on tangent and superelevated on the outside of all curves. On curves of about 500-ft radius, the superelevation is a maximum of $\frac{3}{4}$ in. per ft. The transition from crowned to banked roadway is at a rate which will maintain a gutter grade of not less than 0.5% nor more than 6%. In the circular tunnel sections the side-walls are normal to the transverse slope of the banked roadway; and, in the steel bent and concrete sections, the side-walls are vertical and side clearances are increased as necessary.

The walls of the tunnel are finished with ivory-tinted, ceramic, vitreous, semi-mat glazed tile with a diffused light reflection factor of 0.78. There is a continuous border of ming green tile at the ceiling.

The tunnel ceiling is finished with 6-in. by 6-in. light ivory-tinted pebbled glass tile set in copper alloy grippers in the ceiling slab.

The tunnel sidewalk bench is faced with light, buff-tone, mottled glazed, architectural terra cotta. A sidewalk railing 2 ft 3 in. high is composed of cream-colored, porcelain enameled steel pipe 1½ in. in diameter.

FIG. 8.—TYPICAL PLAZA CROSS SECTIONS

The recessed light boxes for tunnel lighting have bronze fronts, and all niche and accessory doors are of commercial and extruded bronze shapes. All finish and hardware in the tunnel are flush, and signals are streamlined so as to facilitate washing and cleaning operations.

Plazas and Approaches, Manhattan.—Two types of design were studied for the Manhattan plazas. One type employed a drainage system under a comparatively thin invert slab, through which the underground water would be conveyed to a main drainage gallery and from there into the sumps to be removed by pumping. The other type of design utilized the weight of walls and heavy invert slab to counterbalance hydrostatic uplift, and, as construction costs would have been about the same in either case, this latter design was adopted as the more reliable.

In general, the typical cross section of each plaza is that of a U-shaped reinforced concrete structure in a waterproofing envelope with concrete protection outside the waterproofing (see Fig. 8). Invert slabs vary in thickness from 8 ft to 1 ft; the retaining wall height above the roadway is a maximum of 22.5 ft at the entrance portal and 31 ft at the exit portal. Invert subgrade is partly in rock cut and partly above rock surface elevations. In practically all cases, retaining walls were extended down to rock. For an area of the entrance plaza under which the overburden of rock contained layers of peat, the invert slab is supported on piers carried down to the rock. The invert slabs of both plazas are divided by expansion joints placed at 50-ft intervals; these joints are filled with premolded cork filler and provided with copper water stops.

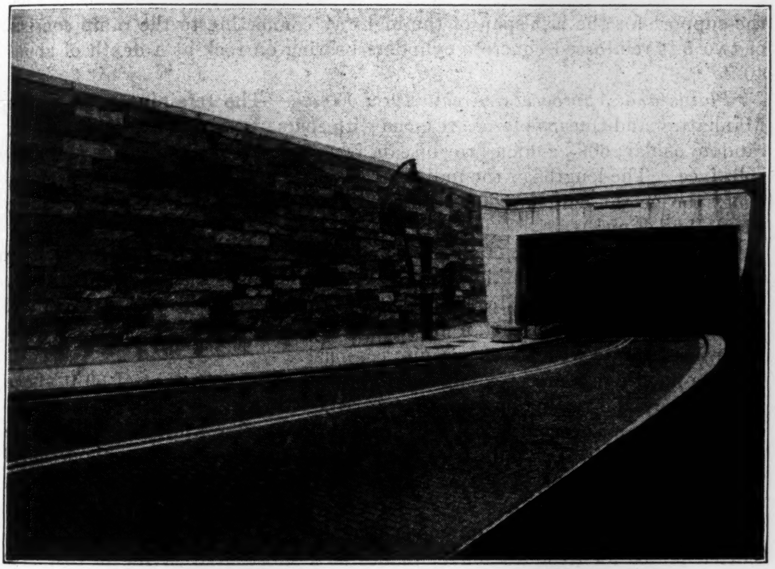

FIG. 9.—PLAZA WALL FINISH AT MANHATTAN ENTRANCE

The exit plaza underpass at Second Avenue is of the steel bent and concrete subway type of structure, as is the underpass under 36th Street.

The north and south tunnel entrance and exit avenues in Manhattan provide 32-ft roadways and a sidewalk generally 4 ft 4 in. wide on the side to the right of the direction of travel of each roadway. When practicable, the foundation walls of the demolished improvements were utilized for foundations of the parapet walls. In other instances the walls had to be built to retain high ground of adjacent areas.

Plazas and Approaches, Queens.—The Queens plaza may be considered structurally as consisting of two sections. The west section between the portal at Vernon Boulevard and 11th Street, where the roadway comes to grade, is similar in design to the Manhattan plazas. The east section of the plaza, starting at 11th Street and continuing to 21st Street and 50th Avenue, is constructed on compacted backfill contained by L-shaped reinforced concrete walls located on the south side; the roadway pavement is a reinforced concrete slab 10 in. thick laid directly on the backfill.

The east section of the plaza includes a ramp leading to the elevated express highway. Because the bearing capacity of the soil was found to be unreliable, the support for the last span of the highway connecting to the ramp consists of two 5-ft reinforced concrete cylinders bearing on rock at a depth of about 40 ft.

Plazas and Approaches, Architectural Finish.—The retaining walls of the Manhattan and Queens plazas are faced with coarse-texture, seam-face, granite, random ashlar; 60% golden-brown seam face, 20% bright seam face, and 20% split face. The lengths of the individual stones are as much as 8, and even 10, times the height, emphasizing the horizontal lines of the plazas (see Fig. 9: Plaza Wall Finish).

The tunnel portals are of six-cut Moose-a-bec granite with polished granite cheeks extending 20 ft into the tubes, and finishing flush with the tunnel tiling. The Queens portal is a twin design with exceptionally large pieces of granite. The soffits of the Manhattan portals are arched. Parapet walls are solid seam-face granite with six-cut granite copings.

The flood lights are of commercial type, placed at a height of 60 ft above the roadway and resting on granite pedestals.

Buildings.—The ventilation buildings of the Queens Midtown Tunnel (see Fig. 10) are classified as industrial power house structures. They are designed with structural steel skeleton frames and are of fireproof construction throughout.

A distinct departure from previous designs was the development of masonry-slotted jambs for fresh air louver blades at a substantial saving in cost over the all-bronze louver construction. The louver blades are ebony asbestos cement slabs impregnated with waterproof compound of fluxed natural asphalt.

The Manhattan ventilation building is 110 ft by 144 ft and is 124 ft high to the top of the two exhaust, or evasé stacks, which rise 14 ft above roof level. The building, which has an octagonal shape, is partly supported on the Manhattan ventilation shaft structure and partly on piers based on rock. This building houses twelve fresh air supply fans and twelve exhaust fans, a large switchboard room, transformer compartments, carbon-monoxide analyzer room, chemical room, maintenance rooms, electrical work shop, pressure-tank room, and elevator motor room. Two enclosed stairways and an elevator in the building provide access from the tunnel roadways to all floors. The cubic-foot cost of the building was $0.439, not including the cost of foundations or rough first floor slab.

The Queens ventilation building, which is partly supported on the bent structure of the tunnel and partly on concrete-filled steel cylinders, is 107 ft by 113 ft in plan with a height of 121 ft to the top of the evasé stacks, which rise about 30 ft above the roof level. Its structural and architectural treatments are similar to those of the Manhattan building. Eleven fresh air supply fans and eleven exhaust fans are housed on three floors, and other equipment and facilities are as for the Manhattan building. Exclusive of foundations and rough first floor slab, the cost of this building was $0.404 per cu ft.

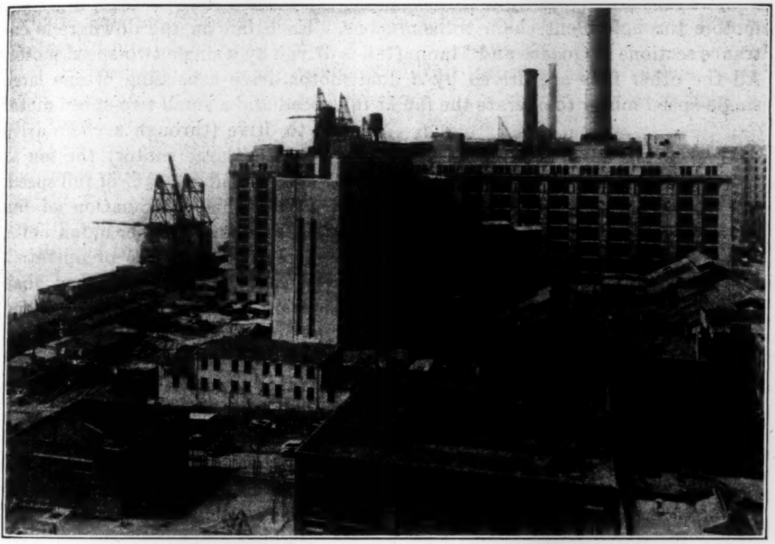

FIG. 10.—MANHATTAN VENTILATION BUILDING, NEARING COMPLETION

The service building in Queens is approximately 100 ft by 185 ft in plan, and is a single-story structure housing shops and a garage for maintenance equipment and two stories and basement housing the rooms for supervisory control, electrical equipment, police quarters, detail room, and maintenance and operating offices. The cubic-foot cost of this building was $0.543.

TUNNEL VENTILATION

The method of ventilating the Queens Midtown Tunnel follows closely that developed for the Holland Tunnel. A continuous supply of fresh air is introduced to the driveway just above the curb through fresh air flues generally spaced at intervals of 10 ft 8 in. on upgrades and level grades, and 16 ft on downgrades, on each side of the roadway, locations on opposite sides of the roadway being staggered. These fresh air flues are fed from a longitudinal supply duct under the roadway. The vitiated air is removed through exhaust air ports placed at similar intervals in the roadway ceiling slab, above which is the longitudinal exhaust air duct.

Each tunnel is divided into four separate ventilating sections. With the exception of a short ventilating section on the Queens end of the north tunnel, which has two fresh air fans and two exhaust air fans, all the ventilating sections are connected to three fresh air fans and three exhaust air fans.

For normal maximum ventilation requirements, fifteen fresh air supply fans and fifteen exhaust air fans are operated. The remaining sixteen fans are stand-by spares.

The fans are driven by totally enclosed, fan-cooled, squirrel-cage, induction motors through silent chain transmissions. Each fan on the downgrade entrance sections in Queens and Manhattan is driven by a single two-speed motor. All the other fans are driven by a dual motor drive consisting of one large single-speed motor to operate the fan at full speed and a small two-speed motor to drive (through a chain drive to the large motor) the fan at $66\frac{2}{3}\%$ and at $33\frac{1}{3}\%$ of full speed. With this combination of fan speeds and number of fan units, greater economies of operation have been accomplished than were possible at the Holland Tunnel where the fans are driven by slip-ring motors of the wound rotor type with external resistance for varying the speed.

During 1941 when approximately 4,400,000 vehicles were carried by the tunnel, of a total electric power bill of $33,412.35 (which was mostly for lighting), only $4,704.30 was for ventilation, or a rate of about 0.1¢ per vehicle. Table 1 is a comparison of the salient features of the ventilating system of the Holland Tunnel and the Queens Midtown Tunnel.

TABLE 1.—COMPARISON OF VENTILATION; QUEENS MIDTOWN AND HOLLAND TUNNELS

(Twin Tunnels in Each Case)

No.	Description	Holland	Midtown
	Length of Tunnel, in Feet:		
1	North	8,557	6,414
2	South	8,371	6,272
3	Total ventilated	16,928	12,686
	Number of:		
4	Ventilation sections	14	8
5	Ventilation equipment, buildings	4	2
6	Fresh air fans	42	23
7	Exhaust air fans	42	23
8	Electric motors	84	82
9	Air changes per hour	42	42
	Volumes, in Cubic Feet per Minute:		
10	Fresh air supplied	3,765,200	2,889,000
11	Air exhausted	3,915,600	2,954,000
	Fan Brake Horsepower Installed:		
12	Total	6,260	4,118
	Normal Maximum Operating Fan Brake Horsepower:		
13	Total	4,173	2,725

TUNNEL LIGHTING

The tunnel is lighted by means of individual luminaires along the walls of the tunnel, immediately below the ceiling. Each luminaire contains a 150-watt and a 100-watt incandescent lamp on independent circuits. Three levels of illumination are used according to the intensity of daylight outside the tunnel. Additional illumination during the daytime inside the entrance portals is provided by 1,000-watt and 500-watt enclosed fixtures suspended in open bays in the ceiling of the tunnel, graduated from five 1,000-watt fixtures per bay at the portal to three 500-watt fixtures per bay at 160 ft inside the portal. The graduation of light at the portals, produced by this additional illumination in combination with the three levels of tunnel illumination, has eliminated the discomfort and blinding effects experienced by motorists on entering other vehicular tunnels.

Lighting circuits are arranged so that a motorist is always within the light of luminaires fed from four sources of power regardless of whether the 150-watt lamps or the 100-watt lamps are burning.

TUNNEL OPERATION

The central point of control of operation is in the service building, which contains the electrical control board from which ventilation fans are started and stopped and their speed changed, from which the traffic signals and alarms for both fires and wrecks are piloted and controlled, and from which the intensity of tunnel lighting is varied.

The board also carries the carbon-monoxide recorders of the various ventilation sections of the tunnel and indicators of the rate of flow of vehicles in each tunnel.

The personnel attending to the movement of vehicles functions as a private uniformed police force supervised by a captain who reports to the superintendent. The mechanical, electrical, and structural maintenance force reports directly to the superintendent. The operating staff was organized under the direction of the chief engineer and, after six weeks of successful operation, was turned over to the direction of the administration department.

The arrangement of the organization, which was an innovation over other tunnel projects, has proved itself to be sound and economical. The cost of operation during 1941 was $587,916.22, or less than 40% of the cost of operating the Holland Tunnel.

CONSTRUCTION

Construction Program and Costs.—The construction work of the project was divided into thirty-one contracts, including three for test borings; and, in addition, there was a miscellaneous group of contracts and open-market orders for operating equipment. A coordinated program for preparation of plans, contracts and specifications, advertising, opening bids, awarding, and times for completion of these contracts, was prepared when work began on the project. This schedule, of course, was subject to some modification and revision from time to time to suit varying requirements and conditions as the work progressed, but the essential principle of the program was successfully adhered to—that is, to complete the construction of the project in the minimum time practicable, with an accumulation of payments to contractors for the work as completed, which would result, as nearly as possible, in a minimum total for interest during construction.

All work was let under open competitive bidding and the contracts were awarded to the lowest responsible bidder. In all cases, this was the low bidder, with the exception of contract No. 2-A for borings at the site of the Manhattan ventilation shaft where the low bidder was unable to start work as ordered because of inability to obtain labor of the required type.

Table 2 gives a list of the contracts for the project, together with final costs, and the dates of beginning and completing the field work. The dates for completion are the actual dates when all work under each contract was fully completed and accepted, in some cases extending beyond the date of opening the tunnel.

The first construction contract to be let was No. 1, and the second, No. 3. The individual letting of these contracts permitted work to progress on them while plans, contract, and specifications were completed for contract No. 4, the principal contract of the project. When contract No. 4 was let, the construction shaft in Queens had been completed and was ready to serve as the point of operations for tunneling from Queens; tunneling operations from Manhattan were started in the ventilation shaft excavated under contract No. 3 and, later, were transferred to construction shafts sunk to the west of the ventilation shaft, thus permitting work on the Manhattan ventilation building to proceed. With the letting of contracts Nos. 7 and 8, the entire main structure of the project from portal to portal was placed under construction. All remaining contracts were coordinated to contracts Nos. 4, 7, and 8. Work on the Manhattan ventilation building was suspended from August 14, 1939, to November 1, 1939, and on the Queens ventilation building from February 17, 1940, to May 27, 1940, while ventilation equipment was being installed.

TABLE 2.—TIME OF START AND FINISH AND COST OF CONTRACTS ON THE QUEENS MIDTOWN TUNNEL

Contract No.	Description of work	Started	Finished	Total cost
1	Queens construction shaft	Oct. 5, 1936	June 9, 1937	$ 201,074.06
2	Land and river borings	Oct. 13, 1936	Jan. 13, 1937	49,585.17
2A	Manhattan shaft borings	Oct. 2, 1936	Oct. 10, 1936	3,644.57
2B	Manhattan plaza borings (modified to include Queens plaza borings)	Oct. 4, 1937	Nov. 30, 1937	4,477.55
3	Excavation for Manhattan ventilation shaft	Jan. 4, 1937	July 29, 1937	299,332.34
4	River tunnels and shafts	July 14, 1937	June 3, 1941	22,133,304.32
4A	Dredging and pile driving	Sept. 14, 1938	Nov. 17, 1938	63,449.60
5	Manufacture, storage, and delivery of cast-iron tunnel lining	Jan. 4, 1937	Oct. 31, 1939	3,333,587.58

18D	Manhattan plaza finish	Nov. 20, 1940	June 19, 1941	249,196.91
19	Service building and Queens emergency garage	May 23, 1939	Oct. 30, 1940	296,911.36
20	Tunnel and plaza paving	July 12, 1940	Dec. 10, 1940	193,026.67
	Total contract costs	....	....	$38,888,701.38

Work on the site of the project was conducted under the rules and regulations of the PWA specifying minimum wages and maximum hours of work—the 30-hr week, applying to contracts Nos. 1 to 3, inclusive, and, by special dispensation, the 40-hr week to contracts Nos. 4 to 20, inclusive.

Total contractors' labor for the project amounted to approximately 9,193,000 man-hr at the site, at an average hourly wage of $1.61. For contract No. 4 alone, the total man-hours were 5,942,000 and the average hourly wage was $1.78. These figures for man-hours and average hourly wages are based on the actual working hours and hourly wages paid, including the net work-shift hours of compressed-air workers whose wages were on a daily basis.

Shafts.—In Queens, tunneling operations for the river tunnels were conducted through a working shaft located on the center line of tunnels 260 ft east of the east building line of Second Street. The shaft was 86 ft 9 in. by 33 ft 9 in. and was excavated to subgrade depth at 67.4 ft below street surface. The shaft structure was of steel and concrete. Two octagonal openings, exposing the rock wall of the excavation, were provided on 45-ft centers in the west wall of the shaft through which to drive the tunnel shields.

The Manhattan ventilation shaft was excavated to net lines 60 ft 2 in. by 111 ft 8 in. in plan and an average depth of 112 ft below ground surface, the excavation being mostly in rock. The shaft was used for initial tunneling operations and, as a precaution during this period, lined with a designed minimum thickness of 4 in. of protective concrete reinforced with wire mesh, and the walls were braced temporarily with timber frames.

The two construction shafts in Manhattan, to which tunneling operations were transferred, were 25 ft by 25 ft in plan, and centered on the tunnel lines an average distance of 112 ft west of the center of the ventilation shaft. The shafts were excavated to a depth of 4 ft below the tops of the respective tunnels, and the rock headings from the ventilation shaft driven through them.

River Tunnels.—Construction of the river tunnels only will be discussed in this paper as the limitation of space will not permit any further discussion of the other contracts of the project.

In the New York area, three large diameter tubes comparable in size to those of the Queens Midtown Tunnel—Holland Tunnel (two tubes, 29.5 ft in diameter) and the south crossing of the Lincoln Tunnel (one tube, 31.0 ft in diameter)—had been driven successfully in the bed of the Hudson River. On the other hand, the experiences in tunneling under the East River, to 1937, had been gained mainly with rapid transit tunnels, 18 ft 3 in. or less in diameter, and with the four tubes for the Pennsylvania Railroad,[4] 23 ft in diameter. The latter provided the best available basis for comparison in anticipating construction conditions in the Queens Midtown Tunnel. Uncertainties in connection with driving the substantially larger 31-ft tubes through the porous overburden and varying rock conditions of the bed of the East River contributed to a narrowing of the field of competition for contract No. 4, for which only two bids were received. The Walsh Construction Company, low bidder, was awarded the contract and completed the work well within schedule.

Contract No. 4 extended between limits 4,086 ft apart in the south tunnel and 4,111 ft apart in the north and comprised all of the shield-driven, cast-iron-lined tunnel of the project (3,772 lin ft in the south tunnel and 3,756 lin ft in the north); part of the rock tunnel lined with 32 ft 10 in. structural steel

FIG. 11D.—LONGITUDINAL SECTION SHOWING PROGRESS OF RIVER TUNNELS; STATIONS 60+0 AND 65+0

(225 lin ft in the south tunnel and 265 lin ft in the north); completion of the Manhattan ventilation shaft structure to surface line; and the necessary work in the Queens construction shaft. Prices for tunnel excavation east of the Manhattan ventilation shaft under this contract were as follows: Earth, $62.00 per cu yd; rock, $52.50 per cu yd; and mixed face, $96.00 per cu yd. These are the highest unit prices for tunnel excavation in any corresponding quantities that have come to the writer's attention and reflect the uncertainties and difficulties anticipated in connection with driving such large-diameter tubes under the adverse ground conditions of this part of the East River.

Figs. 11 show progress in tunneling, together with materials penetrated, air pressures, point of balance of hydrostatic head, and sequence of placing and removing clay blanket. Weekly progress is shown for the advance of the shields. The junction between steel and cast-iron lining is 115 ft east of the Manhattan ventilation shaft in the north tunnel and 85 ft east in the south. The legend for Figs. 11 is as follows:

In Manhattan, the procedure was to drive the rock headings from the ventilation shaft (Fig. 11A), west to the limits of the contract and east to the beginning of cast-iron-lined tunnel. The shields were then erected and equipped at the bottom of the ventilation shaft and advanced in the excavated headings a sufficient distance to permit construction of the tunnel bulkheads. With the tunnel bulkheads in place, bottom drifts were excavated in free air as far as rock cover would permit. Then, the shields were advanced completing the full face of excavation and erecting the permanent cast-iron lining, compressed air being placed on the headings when test drilling encountered soft material. Operations were transferred to the construction shafts on March 31, 1938.

From the Queens side (Fig. 11D), bottom drifts were advanced from the construction shaft for 1,119 ft in the north tunnel and 1,056 ft in the south tunnel (to about Station 55+0, Fig. 11C), where the rock floor dropped off in elevation rapidly. Compressed air was required in short stretches in each drift just west of the construction shaft, because of a dip in the rock floor there, the soft ground in the upper part of the drift being supported by liner plates. The remaining lengths of the drifts were excavated in free air and driven as high as safe rock cover would permit. The drifts were excavated to subgrade and concrete cradles were constructed on which to advance the shields, which were erected and equipped in the construction shaft. Shield driving, excavating full section, and erecting cast-iron lining were started under air pressure, work being conducted through an air deck placed on the construction shaft. When the shields were advanced sufficiently, the headings were bulkheaded with 12-in. concrete walls placed against the breasting, air pressures were reduced to normal, the shaft air deck was removed, the tunnel bulkheads and locks were placed, air pressure again was placed on the headings, and shield driving was resumed.

Excavation from the Manhattan side was stopped in the south heading on September 26, 1939, and in the north heading on October 7, 1939. Excavation from the Queens side was continued until the holing through in both headings on November 8, 1939. The shields were brought together and all but the steel skins removed, closure rings erected, tunnel lining cleaned and calked, and the interior concrete lining placed, progressing with concreting from Manhattan to Queens.

It was necessary to deposit a temporary clay blanket on the bed of the river in both the west and east channels, in advance of the headings. The riprap shoulders of the permanent blanket in the west channel were placed first. When tunneling was completed, all temporary clay was removed, and dredging was carried down so as to permit placing 5 ft of riprap at required channel depths to complete the permanent blanket.

Altogether 289,330 cu yd of material were placed in the west channel. Some of this was dredged and reused in the east channel, where the total clay deposited amounted to 125,000 cu yd. The blanket was approximately 140 ft wide at the top, with slopes of 1 on 4, or flatter at the sides, averaging about 285 ft in width, toe to toe, with a maximum of 480 ft.

Each of the four tunnel shields was 31 ft 8 in. in outside diameter, the lower half having an over-all length of 15 ft 10 in. from end of tail to cutting edge. Fig. 12 is a view of the shield for the south tunnel, Manhattan. Above the horizontal diameter at the front end, the hood projected 2 ft 10 in., making the upper half of the shield 18 ft 8 in. long. The inside diameter of the tail of the shield was 31 ft 2 in., providing a 1-in. clearance all around the outside of the 31-ft tunnel lining. The thickness of tail was 3 in., and the clearance from the face of the shoving jacks to the end of the shield was 6 ft 4 in.

Ring girders, 5 ft $2\frac{3}{4}$ in. on centers, and horizontal and vertical struts formed the intermediate section of the shield which was divided into thirteen pockets. Above the springing line there were eight working pockets with sliding platforms, each of which was operated by a 96-ton jack. Below the springing line a large center pocket 10 ft $9\frac{7}{16}$ in. high and 8 ft 8 in. wide permitted access of a mucking machine to the face of excavation. The upper two of the remaining four pockets were provided with sliding platforms and jacks as were those above the springing line. Each shield was equipped with sixteen hydraulic face jacks, twelve of 50-ton capacity and four of 96-ton capacity; and there were two 96-ton hydraulic jacks carrying a waler beam for bracing the face at about midheight of the center bottom pocket. Twenty-eight hydraulic jacks 10 in. in diameter were provided for shoving the shield, generally operated at a pressure of 5,000 lb per sq in., and a hydraulic erector arm was provided at the axis of the shield for erecting the lining segments. The face jacks and sliding platforms of the shields were effective in supporting the face of excavation under very difficult conditions, while the large bottom pocket permitted machine mucking in all materials encountered.

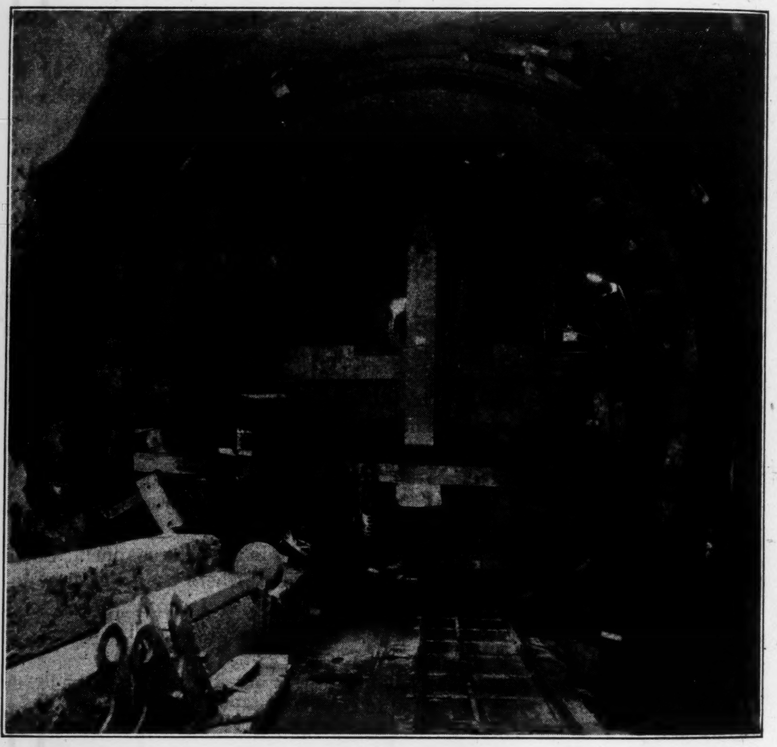

FIG. 12.—REAR VIEW OF SHIELD, SOUTH TUNNEL, MANHATTAN

Tunneling operations were generally conducted on a 24-hr-per-day basis, six days per week.

Whenever practical, bottom drifts were driven in rock in advance of the shields (see Figs. 11). Bottom drifts on the Manhattan side ranged in size from

15 ft wide by 8 ft high to 22 ft by 22 ft; in Queens, it was possible to enlarge the drifts in advance of the shields to full section in some instances.

The tunnels were supplied with low-pressure, compressed air through 14-in. pipes, extending in duplicate from the compressor plants on the surface to each heading. The equipment of the Manhattan compressor plant was typical of both plants and consisted of seven low-pressure air compressors with a total capacity of 40,930 cu ft per min of free air, and three high-pressure air compressors with a total capacity of 6,000 cu ft per min. The high-pressure supply could be used to supplement the low-pressure supply and in the specifications—which required a minimum low-pressure air capacity of 45,000 cu ft per min of free air at a gage pressure of 50 lb per sq in., for each side of the river—80% of the high-pressure air capacity was allowed in computing the low-pressure air capacity of the plant. Three independent sources of power were provided in Manhattan with three separate 13,800-volt electric feeders. In Queens, there were three separate feeders of 27,000 volts each. Adequate capacity and continuity of supply in the low-pressure compressed air plants were vital factors in the successful completion of tunneling operations.

Operations in mixed face consisted, in general, of excavating and breasting the face at the plane of the front edge of the hood down to rock surface. The breast boards were 2-in. or 3-in. planks and were supported by vertical "soldiers," face jacks, and sliding tables. The rock face was excavated sufficiently by drilling and blasting to permit the cutting edge at the bottom of the shield to advance a ring length. If rock extended above the springing line, it was drilled and shot out around the hood just before making the shove. When there was no bottom drift, the shield cradle was made up of concrete-filled burlap bags.

In full face of earth, depending on the nature of material in the lower quarter of the face, the breasting was extended down generally from 6 ft to 12 ft below the springing line, averaging about 7.5 ft. When boulders were encountered in the lower part of the face, the breasting had to be extended down almost to the bottom of the heading. The face was breasted down in the plane of the edge of the hood, and, when the shove was started, the top boards were gradually removed and the material broken down to permit the advance of the hood cutting edge.

The most unfavorable conditions were encountered on the Manhattan side where riprap and other very porous materials in the upper part of the face permitted the compressed air to escape in large quantities, particularly in the area just outside the river bulkhead, where, in order to avoid difficulties with piles, the wharf over each tube had been demolished, the piles pulled out, and a heavy clay blanket placed prior to tunneling. Here, the shields were being advanced in mixed ground, excavating full face with each shove. The consumption of compressed air became dangerously near the full capacity of the plant, including that of the high-pressure air supply. Power consumption was at the rate of approximately 70,000 kw-hr per day. (The power bill for the plant, under these conditions, averaged approximately $4,900 per week.) Air blows through the blanket in the area of the demolished wharf were serious, and so eroded the blanket as to require its constant replacement. The north tunnel was shut down from June 16, 1938, to June 21, 1938, and the heading grouted up with volcanic clay, but the loss of air upon resuming operations in both headings was as great as ever.

On Sunday, June 26, 1938, at 8 p.m., a fire of undetermined origin was discovered in the north heading on the Manhattan side. The north and south headings were about abreast at this time (Fig. 11A). The fire was extinguished by lowering the air pressure and thereby flooding the tunnel at 8:30 a.m., June 27. Before successfully recovering the heading, the material adjacent to and in front of the north shield was grouted through eight 2½-in. casings driven from the river surface, using 4,157 bags of mortar cement in a 1 : 1 mix with beach sand. The heading was dewatered on August 8, 1938, disclosing an inflow of grout and muck at a maximum depth of 14 ft at the shield and running back a distance of 208 ft in the tunnel. After cleaning up, repairing equipment, and grouting the face thoroughly, progress was resumed on August 18, 1938.

Slow progress in the south tunnel (Manhattan end) was continued while the north tunnel was shut down, a total advance of 85 ft being made from June 26 to August 18. Volcanic clay and a volcanic clay-sawdust mixture were used in grouting through pipes in the heading and also through the tunnel lining to consolidate the face and cut down the escape of compressed air. On Sunday, July 17, 1938, the south tunnel was flooded to within 9 ft of the roof after a movement of the bracing at the heading resulted in rapid lowering of air pressure. From August 1 to August 10, inclusive, while the face was grouted (Fig. 11A), no advance was made in the south shield.

Tunneling conditions improved on the Manhattan side as the shields entered the permanent blanket area of the west channel. Tunnel progress from Queens, as shown on Figs. 11D and 11C, was considerably faster than from Manhattan, the material encountered being less pervious, and the air consumption much less than plant capacity; at maximum, compressed air consumption in Queens amounted to 17,250 cu ft per min of free air for the two headings (about April 5, 1939—Fig. 11C).

Excluding shutdowns and abnormally fast or slow progress, normal average progress in the shield headings, in feet per 24 hr, was:

Material	Progress
Earth	7.4
Rock	3.2
Mixed face	3.7

Based on total elapsed time, the average progress for tunneling in the river headings was 18 ft per week per heading. This over-all average includes the time for erecting shields and transferring to shield operations from rock tunneling operations, as well as all other suspensions of progress, including those due to labor disputes. (One period of suspension due to a jurisdictional dispute involving out-of-town work which had no relation to the project resulted in no progress from 8 a.m., Monday, July 3, 1939, to 8 a.m., Wednesday, July 19, 1939.)

The haulage system in the tunnels and on the surface was by storage-battery locomotives, operating on narrow gage tracks. Steel cages, shaft ways, and headframes were installed at the construction shafts, two cages, 8 ft wide by 20 ft long with a 100-cu-yd muck hopper between them, being located on each side of the river. In the tunnel heading, the mucking machine loaded directly into 2½-cu-yd muck cars. The contractor had planned to load from the mucking machines into specially designed conveyors, which would have permitted continuous loading of the cars. However, very little use was made of the conveyors, because of union stipulations as to their operation to which the contractor would not agree and which apparently outweighed their advantages. The tunnel cars dumped directly from the cages into the hoppers; disposal was by truck.

The cast-iron lining segments for each ring were loaded on flat cars, cleaned on the surface, and delivered to the heading with the necessary grommets, washers, and bolts. The segments were lifted from the flat cars by monorail hoist behind the grouting platforms and skidded along the track rails to the erector. The lining bolts were tightened by hand. Before shoving the shield for the next ring, all bolts in the two preceding rings erected were re-tightened. The annular space between the tail of the shield and the last ring erected (a source of considerable air leakage) was calked with burlap bags.

As soon as practicable, during the erection of each ring, a 2-in. turnbuckle was placed on the back flange of the ring at the horizontal diameter. Turnbuckles were removed when observations indicated that any tendency of the ring to flatten had stopped.

The turnbuckle brackets also served as supports for the working platforms, which were towed behind the shield. Each of these platforms had two levels, one about 6 ft above the other, and, by means of the platform adjacent to the shield which was 15 ft long, access to the tunnel lining for erection, bolting, grouting, and graveling operations was obtained. The second platform, about 30 ft long, followed a few feet behind the first and carried grout pans, gravel pans, and materials, and served in connection with these operations. The monorail hoist, which was used to unload the cast-iron-lining segments, also served for carrying materials from cars to the working platforms and shield.

When the tunnel was in soft ground or mixed face, gravel was ejected from the grout holes of the lining to fill the annular space left by the tail of the shield, or the space between the rock and lining, starting at the bottom and working up on both sides of the tunnel to the three-quarter points or to top of rock when rock extended higher, except in cases where special treatment was desirable. This was followed by grouting up to top of rock, generally using a 1 : 1 mix of portland cement and sand. Both pea and ½-in. gravel were used. In full rock sections, the void outside the lining was completely filled with gravel and grout.

Observations showed that, in general, the heavy lining in full face of soft ground tended to flatten, increasing horizontal diameters over a range of from zero to 1¾ in. (averaging about 1 in.); the opposite was true of the light lining, where horizontal diameters generally decreased after erection over a range of from 0 to 2 in. (averaging about 1 in.). This decrease occurred, as would be expected, when the gravel and grout were placed outside the lining.

Modern cast-iron lining is manufactured very nearly true to theoretical form, and practice in erection would be improved by erecting the lining as nearly to its designed shape (that is, circular) as is practically possible. This would tend to eliminate the localized strains and possible open joints which may result from distorted erection; and, with a uniformly high initial bolt stress, it would be a step in improving the waterproof qualities of the calked cast-iron tunnel ring.

Working conditions and safety precautions in compressed air and tunnel construction were in strict accordance with the best standard practice which included conformity with the Industrial Code.[5] Second tunnel bulkheads were installed in the four tunnels to provide for double-stage decompression (see Figs. 11). Three locks were generally provided in each bulkhead, the muck locks being 10.5 ft in diameter and 35 to 44 ft in length. Man locks were generally 6.5 ft in diameter and 34 ft long, and emergency locks, 5 ft in diameter and 30 ft long. Additional service locks, 5 ft in diameter and 20 ft long, were installed in each of the two first bulkheads on the Queens side.

The maximum air pressure used in tunneling was 37½ lb per sq in. There were 745,480 decompressions with 1,148 reported cases of compressed air illness (mostly mild) with no deaths or permanent ill effects. This record may be compared with that of the Pennsylvania Railroad (East River tunnels), constructed from 1906 to 1908, in which there were 557,000 decompressions and 3,692 cases of compressed air illness, with 20 cases resulting in death.[6]

Upon removal of compressed air and completion of excavation, the tunnel lining was cleaned and calked, and concreting operations, begun on October 17, 1939, were completed on July 11, 1940. Sections of the tunnel prepared for concreting were required to remain absolutely watertight after cleaning and calking for at least one week immediately prior to placing the concrete.

Conclusions

Extended research is no longer necessary in planning and designing tunnels for highway traffic, and, with proper coordination of contracts, such projects can be completed in a practical minimum of time. The operation of existing highway tunnels will continue to provide data for improvements in design which will add to the safety, utility, and economical operation of future tunnels. Although it is possible to construct large-diameter subaqueous tunnels with safety under adverse ground conditions, a field remains for the development of improvements in construction methods which would increase tunneling progress, and reduce construction cost.

Ackowledgments

The Queens Midtown Tunnel was built, and is owned and operated as a toll facility, by the New York City Tunnel Authority, a public benefit corporation created on January 6, 1936, by act of the Legislature of the State of New York. It is authorized to construct and operate, on a self-supporting and self-liquidating basis, certain specified vehicular tunnel projects within the limits of the City of New York. The three commissioners of the Authority (Alfred B. Jones, chairman, Albert T. Johnston (died February 9, 1943), and William H. Friedman, who serve without pay, and under whose tenure of office the Queens Midtown Tunnel has been financed, constructed, and placed in operation) were originally appointed by Mayor LaGuardia in 1935 as the commissioners of the Queens Midtown Tunnel Authority, which was superseded in 1936 by the New York City Tunnel Authority. The writer served as consulting engineer to the Tunnel Authority from 1935 to April, 1936, when he was appointed chief engineer, and in that capacity directed the planning, design, and construction of the project.

---

[6] "Compressed Air Illness," by Frederick L. Keays, *American Legislation Review*, 1912.

During all phases of the work the Tunnel Authority has had the helpful cooperation of the municipal departments and utility companies involved, as well as of the U. S. District Engineer's Office and the representatives of the PWA. This, together with the loyalty and efficiency of the more than three-hundred members of the engineering department and the skill and cooperation of the contractors' organizations, contributed in no small measure to the completion of the project ready for operation ahead of schedule.

For the Tunnel Authority, W. McK. Griffin, M. Am. Soc. C. E., is deputy chief engineer; James H. Dugan, M. Am. Soc. C. E., engineer of design; Jacob Mechanic, Assoc. M. Am. Soc. C. E., engineer of construction; John H. Quimby, M. Am. Soc. C. E., assistant engineer of design; Leo Geenens, electrical engineer; Herbert G. Cruthers, mechanical engineer; Erling Owre, architect; John J. Nanry, M. Am. Soc. C. E., and Denzil W. Coe, M. Am. Soc. C. E., resident engineers; George L. Lucas, M. Am. Soc. C. E., materials inspection engineer; Norman D. Richardson, M. Am. Soc. C. E., engineer of contracts; David G. Baillie, Jr., M. Am. Soc. C. E., assistant to chief engineer; Louis C. White, assistant engineer of construction. Principal consultants were Jesse B. Snow, M. Am. Soc. C. E., consulting engineer; Edward Levy, M.D., medical consultant; and Charles P. Berkey, Hon. M. Am. Soc. C. E., consulting geologist. The J. G. White Engineering Corporation and Gibbs and Hill, Inc., were electrical consultants.

In the preparation of this paper the writer has had the cooperation of many of the key members of his engineering staff, and he is particularly indebted to Mr. Baillie for his valuable assistance.

This paper has been condensed from a more extended one which has been filed at the Engineering Societies Library in New York.

DISCUSSION

Thomas W. Fluhr,[7] Assoc. M. Am. Soc. C. E.—Attention is called in this paper to the difficulties of tunnel work beneath the East River as contrasted with those beneath the Hudson River. This results from fundamental geological differences in the two places.

A gorge, which at some points reaches depths of 300 ft or more below sea level, has been eroded in the bedrock beneath the Hudson River so that, except at the shores, rock lies too deep to affect tunnels of this type. The gorge is filled partly with glacial deposits above which there is a considerable thickness of plastic river silt. A shield penetrating the silt can be bulkheaded off and "shoved blind," displacing most of the silt in its course and allowing only a small amount to enter the tunnel.

In the East River, on the contrary, erosion has not cut so deeply into the bedrock. Moreover, there are several varieties of rock present, differing in hardness and in resistance to erosion. On the Manhattan side of the river there is a hard schist and, on the Queens side, a hard gneiss. A ridge of gneiss also occupies the center of the river, forming, where it reaches the surface, Welfare Island and its associated reefs. The east and west channels of the river are underlain by softer and more easily eroded limestone. In addition to these differences, faulting has produced weakened zones along which erosion has occurred. Hence the elevation of the rock floor varies so that at tunnel level the excavation passed alternately through hard rock, soft rock, mixed ground, and soft ground.

Moreover the overburden in the East River, in contrast to that of the Hudson River, consists largely of compact glacial deposits together with some artificial fill, necessitating complete excavation and breasting before each shove of the shield. Thus progress in East River tunnels is slower and more costly than in Hudson River tunnels.

As an interesting side light, it may be noted that originally it was proposed to locate the Manhattan ventilation shaft and building close to the Manhattan bulkhead. A zone of soft rock, resulting from decay along a fault (see Fig. 11A), was discovered by test borings. In consequence the shaft and building were shifted to a point farther west where the tunnel curves to the south, thus skewing the building in reference to the street system and building lines. In order to avoid the incongruity of a rectangular building at a skew to existing structures, the architect modified the original building design, which resulted in its rather unusual octagonal form.

Howard L. King,[8] M. Am. Soc. C. E.—An invaluable record of a great achievement in design and construction is presented in this paper. Its value is emphasized by the regrettable fact that the Society has published no similar report on the Holland Tunnel or the Lincoln Tunnel.

---

[8] Chf. Engr., Mason & Hanger Co., Inc., New York, N. Y.

The paper bears witness to the thoroughness and wise forethought that characterized all matters of design. The record of construction is not as complete as it might advantageously have been, but this lack is offset by the excellent longitudinal sections showing progress on the underriver section.

The author points out the difficulty of making the light tunnel iron perfectly watertight and attributes this leakage in part, at least, to the fact that the exterior material had no tendency to silt up any small spaces between the abutting iron flanges. The use of a machine is suggested to tighten the bolts in the light iron and thus to reduce the chance of crevices. Another proposal might prove more effective—to supply an outside material that will choke up the crevices.

Light iron is used where the tunnel is located in weak and wet rock. The excavated tunnel is necessarily irregular and is likely to be a foot or more larger than the iron diameter. The annular space between the exterior of the iron and the irregular surface of the excavation is backfilled with half-inch gravel and with portland cement grout or with grout alone. This grout is ejected at a moderate pressure through the tunnel lining; it contains much water; and probably, when it sets, it shrinks and cracks, providing excellent channels for seepage water to follow and to reach the lining. It would not be practicable to regrout with a thin neat cement grout to fill these cracks, using perhaps 500-lb pressure, because such a pressure might crack the iron.

It would be of interest to experiment with backfill of a soft plastic material, such as Hudson River silt or a clay that is free of stones. Probably the material should be delivered in the tunnel in dry, powdered shape. Then it would be mixed in the grout machine to a liquid mass whose water content would be just on the wet side of the liquid limit, and finally the material would be forced through a hose in the same manner as grout. Once outside the tunnel the clay fill would crack if it dried, but, if the section were a wet one, it would remain wet and should act as an effective waterproofing. Perhaps a small admixture of bentonite would be of value.

FRANCIS V. WAGNER,[9] JUN. AM. SOC. C. E.—The relatively meager literature on subaqueous tunneling has been well supplemented by this valuable and comprehensive paper. Inasmuch as its very scope precluded extensive treatment of any one phase, the writer wishes to enlarge on one aspect of the job. The author mentions the unfavorable conditions for compressed air tunneling that existed in the extremely porous ground beneath the Manhattan River bulkhead. When the heading was in this region, the consumption of compressed air increased to an alarming rate, and the bill for electric power to supply it reached the relatively high average of $4,900 per week. This sum, of course, is the result of an unusual situation. A weekly electric bill of $1,750 would be more representative of average conditions. While he was an employee of the New York City Tunnel Authority, a study was undertaken of power-house costs for the construction of the Queens Midtown Tunnel.

Functions of the Power House.—As stated by the author, the primary function of the power house is to supply sufficient air to the heading to maintain the desired pressure. This is known as "low air." However, the power house has several other functions: It must supply compressed air to operate tools and machinery in the tunnel. This is known as "high air" and, since these tools and motors exhaust into the heading, it must be at a pressure of 60 to 80 lb per sq in. greater than that existing in the heading. The power house must also supply sufficient water under a pressure great enough to operate the hydraulic jacks that propel the shield. It must supply direct current for charging the batteries of the electric locomotives used in construction operations and for miscellaneous power.

---

[9] Senior Structural Engr., Brewster Aeronautical Corp., Johnsville, Pa.

Power-House Costs.—The total power-house costs will be the sum of the fixed charges for the entire power house, and the operating costs for each of its functions.

The cost of the land is the first fixed charge that must be considered. If the land is leased, the rent will be a fixed charge. If it is bought, taxes will be in the same classification. The largest charge, of course, is the amortization of the original investment and interest on the capital tied up in it. Although this actually might be done by any of several methods, for the purposes of this study it was considered that this charge was distributed evenly over the entire period during which the power house was supplying low air to the tunnels. Therefore, it was constant.

The cost of insurance, of course, was constant over the period to be studied. Although the charges for light, heat, and incidental maintenance to the building varied seasonably, their relative weight was negligible, and it was considered sufficiently accurate to compute them as fixed charges.

Operating Costs.—The operating costs of the individual functions are composed of the charges for power, and for labor for both operation and maintenance. Some of these costs will be constant and others will be variable.

The cost of power will vary according to the amount of the particular item supplied. The cost of labor will vary according to the amount of man-hours necessary to supply the item. It will not vary, necessarily, with the amount of the item supplied. The usual force in the power house was an engineer, an oiler, a gage tender, and a hydraulic maintenance man. This force was sufficient for all operations and for all ordinary, routine maintenance. It devoted a certain amount of time to each function—supplying low air, high air, hydraulic pressure, and electric current. The fact that the high air compressors were running at three-quarters speed and the low air compressors at half speed, or vice versa, did not, necessarily, alter the distribution of their time between these machines. No records were kept of the actual time distribution of these men. Inasmuch as they were responsible for the entire power house, and distributed their time as they saw fit, it was impossible to allocate this labor cost to each function. Therefore, it was considered as a constant charge.

The only variable charges therefore were the costs of power to supply the various functions of the power house. To consider them in the inverse order of their importance: Direct current was supplied for charging the batteries of the electric locomotives and for other miscellaneous power. When the job was underway, the amount consumed was a fairly constant one. No matter what the type of work in the tunnel, the electric locomotives were kept busy hauling materials and muck, and, consequently, needed recharging at a fairly constant period. Direct current consumption for other miscellaneous power was small and may be considered to be constant. The error, accordingly, will be negligible, if the cost for supplying direct-current power be considered a constant charge.

Variable Costs.—Hydraulic power must be supplied to actuate the various jacks on the shield. This water was stored in two hydraulic receivers, which were kept charged by three 100-hp high-pressure hydraulic pumps. The quantity of water used varied with the number of times the jacks were used. With the exception of a few times when the smaller "face" or "platform" jacks were used, jacks were used only during a shove. The cost of supplying this hydraulic power, therefore, varied with the frequency of shoves. This water was pumped continuously, however, and the amount of power consumed by the pumps was small in comparison with that used for the air. There were two other variable costs: The power to supply high air and the power to supply low air.

High Air Consumption.—An important function of the power house was to supply high air to operate power tools all over the job. Some of this was used on the surface and outside the compressed air chambers and was exhausted to the atmosphere. Much of it was used in the heading, and was exhausted therein, thus augmenting the supply of low air. This quantity, then, was used twice—once as high air for power, and once as low air. Although the amount that was thus doubly utilized varied, on the average it is believed that it amounted to about 70% of the high air compressed.

The high air used on the surface powered various tools in the machine shop and yard. Routine maintenance and repairs required a relatively constant amount. However, when there was much rock in the heading, the sharpening of drill bits increased the consumption of high air in the machine shop.

In the heading high air was used for power for a monorail hoist and for various "tuggers." Inasmuch as these machines were used in routine fashion, the amount of high air consumed in their operation was assumed to be constant. The power wrenches for tightening the bolts in the tunnel lining consumed some high air. The amount used in this manner was governed by the frequency of ring erection, which, of course, is the same thing as the frequency of shoves. This was a very small amount. Somewhat larger consumers of high air in the heading were the power spades and the rock drills; but the largest users of high air were the grout and gravel machines. These were used most, when the heading was in rock. The high air consumption in the tunnel might be expected, accordingly, to vary with the amount of rock in the heading.

The only important factor that might be expected to govern the variation of the cost for supplying high air is the amount of rock in the tunnel heading.

Low Air Consumption.—The amount of low air consumed was equal to that which escaped from the tunnel. As has been noted, the air in a tunnel can escape by four paths. The quantity that escapes by all of those ways is, of course, directly proportional to the pressure existing in the tunnel at the time. The amount that escapes by each of these methods, however, is determined by several other factors as well.

The first way in which low air can escape is by means of the air locks through which men and materials enter and leave the tunnel. The amount lost in this manner is dependent upon the number of times the lock is used.

The second avenue of escape for the low air is through the joints in the iron lining. The volume that leaks through these joints is dependent upon the tightness of the joints; but once through the joints, the air must escape through the ground surrounding the tunnel. The porosity of this ground, therefore, is also a governing factor.

The third way in which this air can escape is through the annular opening between the tail of the shield and the last completed ring of lining. The quantity that escapes in this manner is dependent upon the condition of the opening. It is usually kept "bagged up"—that is, stuffed full of old burlap bags—which reduces the leakage considerably. Again, as in the case of joint leakage, the air must escape through the river bed, and that being the case the porosity of the ground is the determining factor.

The last path of escape for the low air is through the face of the heading itself. Once more it is evident that the condition of the opening governs the volume of air that escapes. If the breasting boards are tight and well packed with bags and salt hay and plastered with clay, leakage will be less than through a more open face. As in the last two methods of escape, however, the air must leak through the ground itself. The character of the soil, then, is once more the dominant factor in any study of the volume of leakage.

It must be evident from the foregoing that any study of the factors governing the consumption of low air must take considerable account of the type of ground traversed by the tunnel. With the exception of that volume lost through the air locks, all the low air consumed escapes through this ground. A consideration of the size of the openings through which the air leaks would lead to the conclusion that most of it escapes in the vicinity of the shield. This view is confirmed by observation of the river surface during the construction of the tunnel. Directly over the shield the surface of the water was in constant agitation due to the escaping air. The limits of the area in which bubbles of air were breaking the surface could be noted plainly from a rowboat, and were even more clearly defined from an elevation. Usually, elsewhere along the line of the tunnel, however, no air leakage was discernible at the surface. It is safe to assume that most of the air that escaped through the ground did so near the face of the heading. The type of ground in the heading was one of the most important factors that governed the consumption of low air. It is to be expected, therefore, that, the other factors being equal, if the heading were in impervious material, for instance, the amount of low air consumed would be less than when the heading was in loose ground.

Factors Influencing Variable Costs.—It has been shown, then, that the variable costs for the power house depended, in the main, upon the consumption of high and low pressure air. The factors which governed such consumption would govern the variable costs. Accordingly, the factors that influenced the variable costs of the power-house operations may be listed. They included the air pressure in the tunnel, the frequency of use of the air locks, and the type of ground in the heading.

Statement of the Problem.—Inasmuch as these variable costs combined with certain fixed charges to comprise the operating costs of the power house, it follows that the operating costs of the power house are dependent upon the same factors. In the end, these factors make themselves felt upon the total costs of power-house operations. However, the influence of these factors may be great or it may be small. The first question which must be answered, therefore, is:

1. What is the extent of the variation in operating costs with the factors which influence them?

Once this question has been answered, a second one presents itself:

2. Is this variation in operating costs of sufficient magnitude to affect the total costs of the power house to any appreciable extent?

Should the answer to question 2 be in the affirmative, a study can be made of the variation in total power-house costs with the factors that influence them.

Method of Attack.—In order to answer questions 1 and 2 for the Queens Midtown Tunnel, a survey was made of the power-house facilities which were set up for the construction of the tunnel. That the headings which were driven from opposite sides of the river might be served, the contractor established a power house for each of the two construction shafts. The operations of the Manhattan power house were highly irregular, and fluctuated considerably due to several blows and fires which interfered with the prosecution of the work, and due to many sudden variations in the character of the material in the heading. On the Queens side, however, operations were fairly constant for considerable periods, and conditions were favorable for the study proposed. The Queens power house was chosen as a basis for the study. All information contained in this study and all data presented herein were obtained from the records of the Queens Field Office of the New York City Tunnel Authority.

First, a profile of the tunnel, similar to Fig. 11, was drawn, showing the variations in strata through which the face of the heading passed. On this was superimposed a progress chart of construction, which fixed the dates during which various conditions of face prevailed in the heading. From a consideration of the profile, and from a study of the Queens power-house records, certain periods were chosen which isolated each of the aforementioned variable factors. Then all the operating data of the power house were compiled into usable form for these selected periods. From a study of such data concerning the isolated factors, the extent of their influence upon the quantities involved and, therefore, upon the operating costs, was determined. The first question then was answered.

Once the influence of the governing factors upon operating costs was known, their influence upon total costs could be discovered, and the answer to the problem could be found.

Running Speed of Compressors.—The study disclosed that the plant rarely operated at more than one third of its full capacity of 64,152,000 cu ft per day. To obtain this quantity of low air, the compressors were run alternately, usually at one-half or three-quarters load, which was not the point of their highest efficiency. Occasionally, however, for short intervals, they were run at full load. It was this peak load which determined the power cost, and, at this peak, the machines were operating at their highest efficiency. The efficiency at which they operated for the remainder of the time was of no importance. In order to avoid all chances of a breakdown, then, they were run most of the time at the lower speeds.

Summary.—It was concluded from the study that, in the case of the Queens Midtown Tunnel, there was no appreciable variation in the quantity of high air compressed. No correlation could be discovered between the quantity of low air consumed and the frequency of use of the air locks, or between the quantity consumed and the pressure used in the heading. Nevertheless, the quantity of low air consumed varied directly with the porosity of the ground in the face of the heading, as measured by the pressure used therein. This is shown in Fig. 13. The unit operating costs of the power house decreased in such proportion to the quantity of low air supplied that the operating costs of the tunnel were constant while it was supplying between 12,000,000 and 20,000,000 cu ft of low air a day. This is shown in Fig. 14.

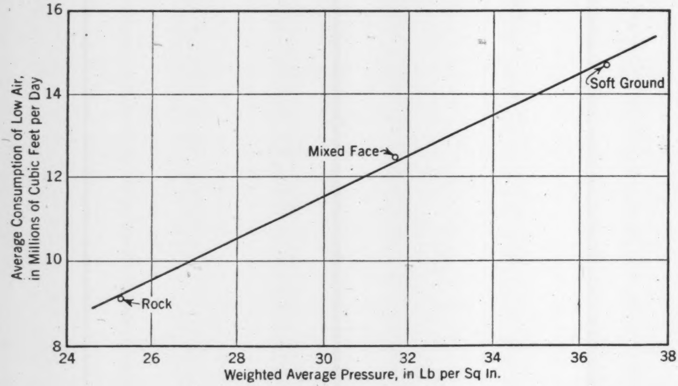

FIG. 13

Power-House Costs.—The total daily power-house cost was constant at $928.27 a day. On the basis of this value, the various elements which constitute it represent the following percentages of the total:

Item	Daily cost		% of total daily cost	
Land	$ 56.563		6.1	
Interest	1.107		0.1	
Amortization	442.638		47.7	
Insurance	6.640		0.7	
Total fixed cost		$506.95		54.6
Labor	178.84		19.3	
Power	242.48		26.1	
Total operating cost		421.32		45.4
Total daily cost	$928.27		100.0	

Trends and Indications.—For the Queens Midtown Tunnel the daily fixed charges were about 20% greater than the average daily operating cost. It would require a fairly large percentage variation in operating costs to cause any appreciable percentage of variation in total power-house costs. This indicated that it is the fixed charges which are important in considering construction power-house costs, and that savings made in them are of more importance than economies in operating expenses. It must be emphasized, however, that the Queens side of this tunnel was in exceptionally good ground for tunneling. It consisted of very fine sand and clay which was not at all porous. In soft ground, therefore, air consumption was relatively low, and, what is more, peak loads were infrequent and were not excessively greater than the average.

Inasmuch as power costs could have been driven sharply upward by an unexpected peak load, the question of maintaining as even a power demand curve as possible is of paramount importance. It must not be forgotten, however, that the low air is a tool that must be used efficiently. Sometimes peak loads are vitally important for economies elsewhere in the work, and then they cannot be avoided. A critical study of the causes of peak loads, with a view to avoiding those which can be eliminated and minimizing those which are unavoidable, would pay handsome dividends in reducing operating costs.

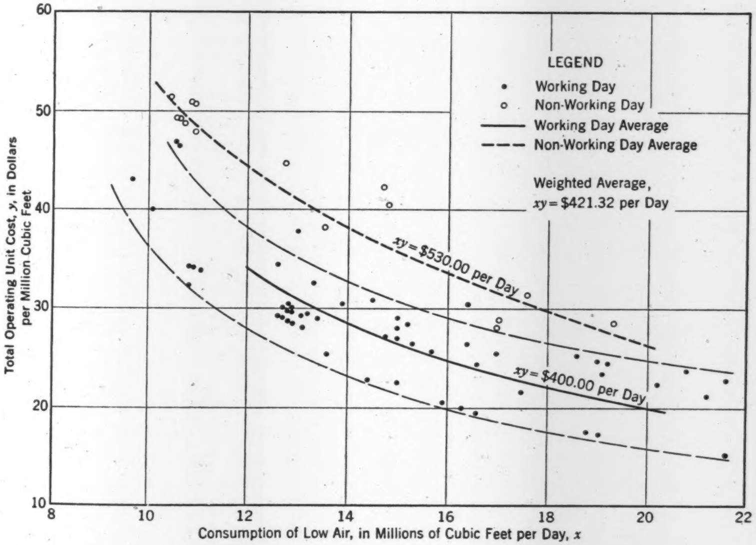

FIG. 14

Acknowledgments.—This study was made in partial fulfilment of the requirements for the degree of Master of Mechanical Engineering, at New York

University, New York, N. Y. The writer is indebted to Prof. A. C. Coonradt, head of the Department of Mechanical Engineering, for his advice and encouragement, and to numerous engineers of the New York City Tunnel Authority and of the Walsh Construction Company, without whose cooperation the study could not have been made. The results were compiled into a thesis: "A Study of Powerhouse Costs for the Construction of the Queens Midtown Tunnel," which is on file in the Library of New York University, and of which the present discussion is a brief summary.

WILLIAM J. WILGUS,[10] HON. M. AM. SOC. C. E.—This is indeed an admirable account of the birth of a star of the first magnitude in the galaxy of great engineering feats that grace the nation's most populous region. Seven monumental bridges for vehicular traffic now span the wide tidal waters encompassing the island of Manhattan on the east and west and between the Bronx and Queens; and, beneath the surface, pass three subaqueous tunnels that serve the same purpose, the one described in the paper being the latest. Between lower Manhattan and Brooklyn a fourth tunnel is in the making, and, beneath the Narrows between Brooklyn and Richmond, a fifth is in contemplation by a method differing from the others. It is to be hoped that more papers will come from the pen of the author, giving the profession the benefit of his remarkable experience in planning, constructing, and operating such public works.

The writer is interested particularly in the happy result that attended the freedom given the bidders, in the case of a part of the Queens Tunnel, to make a selection from specified alternative methods of construction, or, if they preferred, to offer their own solutions on which to base their bids. It happens that the writer took occasion to do this many years ago in the preparation of the preliminary plans and specifications both for the construction of the subaqueous section of the Detroit River railroad tunnel, which resulted in the adoption of his trench-and-tremie method, and for its electrification, which resulted in the selection of the direct-current, third-rail method. Jokingly, this course was referred to, by one of the tunnel bidders, as a "brain poultice," as was true. In a novel situation the bidders, governed by the determined location, gradients, dimensions, and qualities of materials and workmanship, thus are given an opportunity of basing their proposals as to time of performance and costs on methods they consider best qualified for the achievement of the desired end; and the principal is given the assurance of a successful outcome at a minimum of first cost and cost of operation.

In his closing remarks, perhaps the author will give comparisons of leakages and costs per cubic foot of internal content of the subaqueous sections of the Holland, Lincoln, and Queens tunnels—with an index of costs of labor and material predicated on a scale of 100 in the first-named instance. It would be a matter of interest to compare these costs with those for similar work in the past and a help in making rough preliminary estimates for like work in the future.

---

[10] Weathersfield, Ascutney P.O., Vt.

The inclusion of interest on money during construction in the author's statements of cost is of great significance; too often, this is omitted from estimates of the cost of public work to the injury of the taxpayer who thus is misled into believing that his burden will be far less than truth demands. Also, it is gratifying to know that the actual cost of this project was less than the estimated amount. The question may well be asked if the latter is the one that obtained at the outset or was prepared at a later date after unforeseen conditions and difficulties had developed. In public work a suitable provision for contingencies too often is omitted at the beginning because the enlarged figure may scare the public and discourage approval of the project. Utter frankness in these respects is due those who are to pay the bills, as has been shown so obviously in the paper.

In addition to the purpose of the tunnel as a utility, it is evident that sight has not been lost of the esthetic. The interior treatment is most attractive, and the facing of the walls of the approaches with stone gives to them a sense of solidity and comeliness as befits the dignity of a great public enterprise.

S. A. THORESEN,[11] M. AM. SOC. C. E.—The presentation of this valuable contribution reveals the principles of design and construction details that were produced by a staff of engineers with long experience in a specialized field of engineering and construction. The development of vehicular tunnels, being closely related to the increased use of motor vehicles, may be considered a twentieth century product of research and invention. When comparison is made of the modern type of construction with that of Blackwall Tunnel in England, built before the introduction of the automobile, it is apparent that careful thought has been given not only to invite the traveling public for a ride through "a hole in the ground" but also to enjoy an attractively finished, well lighted, pleasant, and comfortably ventilated subaqueous highway.

The construction of the Queens Midtown Tunnel through rock of variable character, with overburden of sand, gravel, and numerous boulders, presented a most difficult problem, and the engineers and contractors entrusted with its execution merit due credit.

Reference has been made to this tunnel as being the first tunnel crossing of the East River for automotive vehicles. In connection with this statement it may prove of interest to review certain historical facts dating back to the beginning of the century, when the first subaqueous rapid transit crossings under the East River were projected and built under the direction of the late William Barclay Parsons, Hon. M. Am. Soc. C. E.

The completion of the Battery Tunnel from South Ferry, Manhattan, to Joralemon Street, Brooklyn, inaugurated the first rapid transit service under the East River, to be followed a few years later by the construction of the Steinway Tunnel from 42d Street, Manhattan, to Long Island City, Queens.

Since the Steinway Tunnel route is in close proximity to that of the Queens Midtown Tunnel, the records kept during the period of construction show certain similarities with respect to the topography of the rock floor and to the deposits of sand, gravel, and boulder formations. On the Manhattan side the tunnel was driven through solid rock and the river section was driven from three shafts, one located at the foot of 42d Street, a second in the middle of the river, and the third in Long Island City. Rapid progress was made by attacking the river part from four faces, and the completion of the twin-tube tunnel during a two-year period from 1905 to 1907 reflects credit on the pioneer engineers and tunnel contractors of that time for a successful and speedy solution under difficult ground conditions full of hazards.

---

[11] Cons. Engr. (Parsons, Brinckerhoff, Hogan & Macdonald), New York, N. Y.

The enterprising spirit and economical prosecution of work in those days (when money was subscribed from private sources) are best demonstrated by actual records, when, in 1906, labor cost for rock excavation under 35-lb air pressure would average from $6 to $7 per cubic yard and the contract cost for this twin-tube rapid-transit tunnel from Grand Central Terminal to Long Island City, 8,500 ft long, was about $5,000,000. The cost of contracts as given by tabulation in the paper is of interest in showing the tendency toward an increase in cost of tunneling under present-day labor, material, and overhead charges, as compared with work performed years ago or during the economic depression. Any combination of construction methods that may reduce costs to a lower level will be accepted favorably, particularly when the total invested capital is supported by toll collection.

Since the construction of the Holland Tunnel (when ventilation research and experimental work were conducted on an extensive scale in collaboration with the U. S. Bureau of Mines), its ventilation system—namely, fresh air beneath the roadway and vitiated air above the ceiling slab—has been adopted in principle by all modern vehicular tunnels.

In Table 1 it is interesting to note the economy of operation brought about by introducing large and small motors for full and partial load conditions as a means of reducing power consumption according to traffic.

Any improvements that tend to reduce the construction cost, and correspondingly the fixed charges must be borne in mind by the tunnel engineer, if the subaqueous highway is to become the means for linking together cities, states, countries, or continents, as the case may be, thus meeting the demands of the future in competition with other methods of transportation.

Postwar problems may well include projects of this character which, in combination with the trench and pre-cast type of design, possess certain economical advantages where soil conditions may favor types of construction such as those adopted for the tunnels under the Detroit River or the Oakland-Alameda Estuary. The latter type of construction has not proved practical for tunnels projected under the Hudson and East rivers but, without doubt, will receive proper consideration in connection with other plans within the New York metropolitan area.

As a monumental structure, the Queens Midtown Tunnel is another contribution to the many underground facilities of Greater New York and, like all great achievements, is an example of organized talent dedicated by the engineering profession to the service of the general public.

H. G. CRUTHERS,[12] ESQ.—The cost of 0.1¢ per vehicle, to provide power for ventilation for the vehicles carried by the Queens Midtown Tunnel, as shown in Mr. Singstad's paper on that project, is extremely low compared to that for similar tunnels and reflects not only a high over-all efficiency for the ventilating equipment but a low cost of power.

For the first year of operation, the actual cost of power for all purposes was 0.9548¢ per kw-hr. This cost included all charges for energy, demand, and fuel and was made possible through purchase from the New York City pool.

The power used for ventilation during 1941, when 4,400,000 vehicles more or less were carried by the Queens Midtown Tunnel, was approximately 0.111 kw-hr for each vehicle. From data available, the power required to provide ventilation for the Holland Tunnel during 1936, when 11,499,000 vehicles were carried by that tunnel, was approximately 0.529 kw-hr per vehicle and for the Lincoln Tunnel during 1938, when 1,790,000 vehicles were carried by that tunnel, approximately 0.289 kw-hr per vehicle.

It has been estimated that, when the Queens Midtown Tunnel carries 11,499,000 vehicles per year, the power required for ventilation will be about 0.10 kw-hr per vehicle.

The number of possible air changes provided for each of these three tunnels is identical (42 per hour) so that the difference in the amount of power required per vehicle carried depends on the method of providing the air changes.

The Holland Tunnel (two tubes) is divided into fourteen ventilating sections, the average length of each being approximately 1,200 ft. The Lincoln Tunnel, a single tube, is divided into five ventilating sections, the average length of each being 1,640 ft. The Queens Midtown Tunnel (two tubes) is divided into eight ventilating sections, the average length of each being 1,590 ft. The areas of the air ducts of the Lincoln Tunnel and the Queens Midtown Tunnel are approximately, for the fresh air ducts, 25%, and for the exhaust air ducts, 20%, greater than those of the Holland Tunnel.

Since the power required to provide ventilation by the transverse method of a continuous rate of supply and exhaust varies inversely as the square of the areas and directly as the fourth power of the lengths of the ducts, it would appear that the power required to provide ventilation for each vehicle carried by either the Lincoln Tunnel or the Queens Midtown Tunnel should be much greater than the power required at the Holland Tunnel. The data show that this is not so—0.529 kw-hr per vehicle at the Holland Tunnel, 0.289 kw-hr per vehicle at the Lincoln Tunnel, and 0.111 kw-hr per vehicle at the Queens Midtown Tunnel. The reason for the lower values for the Lincoln Tunnel, as well as for the Queens Midtown Tunnel, is attributed to the use of higher motor efficiencies at the low-speed operation of the ventilating equipment.

Records from the Holland Tunnel for 1936 operation show that the ventilating equipment was operated for 90% of the time at fan speeds which supplied 29.5% of the normal maximum requirements. Maximum requirements are satisfied by the use of two fans on a duct operating at full speed, and 29.5% of this was obtained at the Holland Tunnel by one fan on a duct operating at approximately 48% of full speed.

---

[12] Mechanical Engr., New York City Tunnel Authority, New York, N. Y.

The records of operation also indicated that for a great part of the time the ventilation requirements were such that much less than 29.5% of maximum requirements would have been ample to provide good atmospheric conditions in the driveways so that, if the ventilating equipment of the Holland Tunnel could have been operated to provide something less than 29.5%, greater economies could have been effected.

With these records of operation as a guide, the Queens Midtown Tunnel was provided with equipment which would allow for operation such that one fan could be operated on a duct at one-third full speed, supplying approximately 20% of maximum ventilation requirements.

At this tunnel, as described by Mr. Singstad, dual-motor drives were installed to operate the fans—one large single-speed motor to drive the fan at full speed and one small two-speed motor to drive the fan at two-thirds' full speed and at one-third full speed. These motors were all totally enclosed fan-cooled squirrel-cage motors with average efficiencies of 92.5% for full speed, 90.7% for two-thirds of full speed, and 85.2% for one-third of full speed, the latter to operate for more than 90% of the time.

At the Holland Tunnel, one slip-ring, wound-rotor motor with external resistance for varying the fan speed was installed to drive each fan. The average efficiencies of the motors were as follows: For full-speed operation, 91%; for 87% of full speed, 78%; for 72% of full speed, 64%; and, for 48% of full speed, 38%.

The difference between motor efficiencies at the low-speed operation of 85.2% for the Queens Midtown Tunnel and 38% for the Holland Tunnel, together with the fact that for a great part of the time ventilation requirements are such that 20% of maximum requirements instead of 29.5% are sufficient to maintain good atmospheric conditions in the driveway, accounts in a large part for the much lower power requirements per vehicle carried—0.111 kw-hr for the Queens Midtown Tunnel as compared to 0.529 kw-hr for the Holland Tunnel.

Dual-drive, squirrel-cage motors also were installed to drive the fans at the Lincoln Tunnel. These motors had operating efficiencies comparable to those installed at the Queens Midtown Tunnel, but the average lengths of ventilating ducts at the Lincoln Tunnel were greater than those of the Queens Tunnel, and, since the Lincoln Tunnel is a single tunnel for two-way operation, the traffic conditions impose a greater load factor; and it is presumed that these two conditions alone account for the difference between the power requirements of 0.289 kw-hr per vehicle at the Lincoln Tunnel as compared to 0.111 kw-hr per vehicle at the Queens Midtown Tunnel.

Leo Geenens,[13] Esq.—The author reports a substantial reduction in the cost of tunnel operation. Approximately three quarters of the operation cost represents wages, mostly of policing, toll-collecting, and maintenance personnel. In general, the greater part of the savings in operating the Queens Midtown Tunnel as compared with the Holland Tunnel is the result of reducing payroll costs. In a large measure this was accomplished through skillful designing based on past operating experience.

---

[13] Electrical Engr., New York City Tunnel Authority, New York, N. Y.

During the design period, the selection and location of apparatus, the selection of materials, and the arrangement of rooms in the buildings were studied in relation to the organization chart for operation adopted at the start of the project. In this chart the personnel was reduced drastically. Man-hours could not be decreased by the elimination of any major operating function but rather by their curtailment on a very large number of relatively small operations. The following are a few examples of the saving obtained in this way in the electrical and mechanical fields:

1. Where possible, operations were made automatic; such was the use of automatic dial telephones to eliminate telephone switchboard operators. In other cases, single operations were made simpler and easier in order to permit employees to take on additional duties—for instance, in the case of the operators attending the main ventilation and traffic control switchboard. This function was combined with the administrative work of the police force and resulted not only in saving man-hours but also in producing a smoother working force with more centralized authority.
2. A reduction in the electrical and mechanical personnel was effected by judicious selection of the apparatus in order that it might function safely without attention for long periods of time. As many as eight operators per shift or a total of thirty-two men (counting relief men) were eliminated in this way. Also the number of maintenance men needed for fans, motors, and pumps was reduced.
3. Particular attention was given to the ever-present problem of corrosion, as painting is a large item of maintenance. Where economically possible, nonferrous metals or materials were used. For instance, as mentioned in the paper, asbestos cement boards were used for baffles and louvres in the ventilation system; all bolts, nuts, screws, washers, and small parts in electrical devices are of silicon bronze; electrical conduits, below ground, are silicon bronze or asbestos cement; electrical relays are sealed in glass containers; motors are totally enclosed; etc.

Many similar reductions were made. For instance, maintenance labor was reduced by a radical simplification of the carbon-monoxide analyzers and recorders. Savings in man-hours have resulted from improved toll-registering machines which have reduced the auditing time. For washing the tile walls in the tunnel, a new machine which does the work faster and with less labor was designed. In order to decrease payroll costs, every operating function was analyzed in the greatest detail.

CHARLES E. CONOVER,[14] M. AM. SOC. C. E.—Under the heading, "Historical," Mr. Singstad states: "In July of the same year [1929], the Board of Transportation was assigned the work of preparing plans and specifications [for the Queens Midtown Tunnel] and starting construction with an initial appropriation of $2,000,000."

---

[14] Cons. Engr., Pearl River, N. Y. (formerly Div. Engr. of Planning and Design, Board of Transportation, New York, N. Y.).

As all who have studied vehicular tunnels know, their success or failure depends largely on the plaza layouts together with the approaches on the assumption, of course, that the development leading up to the plazas warrants the expense of tunnel construction. By approaches is meant not only the streets in the immediate vicinity, but also the traffic arteries that may extend for miles beyond. To illustrate: In the case of the Holland Tunnel the New York City approaches are limited very largely to the lower and midtown areas of Manhattan via adjacent streets and to Brooklyn via Manhattan Bridge, whereas the New Jersey approaches may be considered to extend to, and connect with, every municipality in central New Jersey and even Philadelphia, Pa.

The location of any expensive vehicular traffic facility, whether bridge or tunnel, must be the subject of extensive preliminary investigation, and, as Mr. Singstad has indicated, the Regional Plan Association had made very extensive and comprehensive traffic studies covering midtown Manhattan especially. This research clearly showed the great need, as Mr. Singstad so aptly states, for an east and west traffic axis from Long Island to New Jersey.

The investigations and the plans prepared by the Board of Transportation led to the conclusion that, to render the maximum benefit to Manhattan and Queens and to serve the entire metropolitan area most advantageously, such a traffic axis should have ample and convenient plazas on both the east and west sides of Manhattan and should extend by fairly direct connections far into New Jersey and Long Island. It should provide for express highway service free of the shackles that "stop-and-go" lights impose on fast and continuous service. In practical terms the East River tunnel should so connect with the Hudson River, or Lincoln Tunnel (then being studied, and later constructed and operated, by the Port of New York Authority), that traffic between New Jersey and Long Island could operate across Manhattan without emerging into the street system or in any way interfering with traffic.

Through the splendid cooperation of the engineers of the Board of Transportation with the engineers of the Port Authority, a joint west side plaza was developed, and, through the cooperation of the engineers of the Board of Transportation with the engineers of the Borough of Manhattan, a joint east side plaza was developed.

Although the east side plaza, or the Manhattan plaza, of the New York City Tunnel Authority differed radically from the east side plaza as developed by the Board of Transportation, it retained the possibility of a direct connection with the west side plaza (the Manhattan plaza of the Lincoln Tunnel), and thereby provided the possibility of a direct New Jersey-Long Island highway, if and when the Manhattan tunnels were constructed.

It is to be hoped that the New York City authorities will plan these connecting tunnels as a postwar project. With that connection there should be considerable lessening of crosstown traffic in the midtown Manhattan area, and a considerable increase not only in the traffic of the Queens Midtown Tunnel but also in that of the Lincoln Tunnel. This trend is indicated clearly by the traffic studies of the Regional Plan Association. Further extension into and through New Jersey by express highway or highways also would increase the traffic and relieve local congestion.

In addition, the plans of the Board of Transportation provided an express connection extending several miles into the Borough of Queens, somewhat similar to that mentioned in the paper. That connection should be constructed as a postwar project, as should a viaduct from the Queens plaza crossing Newtown Creek and connecting with the Brooklyn crosstown highway which was under consideration in 1929 and 1930. These connections not only would increase the traffic through the East River tunnels, but would relieve, most assuredly, traffic at and near the Queens plaza.

A detail that should be studied, if and when the Manhattan tunnels are constructed, is the method of connecting those tunnels to the north and south auxiliary streets provided as a part of the Manhattan plaza of the Queens Midtown Tunnel, so that the traffic may move in one direction if reasonably possible. In other words, the auxiliary street east of Third Avenue should be an exit street, not only for the river tunnels, but also for the Manhattan tunnels. Likewise, the auxiliary street east of Second Avenue should be an entrance street for both facilities. The purpose of such an arrangement would be to simplify the flow of traffic at the intersections of the auxiliary streets with cross streets.

In the case of the Queens Midtown Tunnel, the lighting that was developed for the portals where special attention was given to the difficulty of passing between brilliantly sun-lighted plazas on clear days and the more dimly artifically-lighted tunnel portals undoubtedly has resulted in better driving conditions at the portals, than at the portals of the Holland Tunnel.

Under the heading, "Introduction," Mr. Singstad refers to "remote control of ventilation." It is suggested that the designers might have gone a step further and provided not only remote control, but automatic control, of ventilation.

A detail, not mentioned in the paper but which may have been considered, is adequate widening and suitable arrangement at curves to provide for the passage of fire-fighting apparatus. In the plans prepared by the Board of Transportation this matter was given careful attention.

EDWARD LEVY,[15] M. D.—The same high standards of achievement were set by Mr. Singstad for the control of safety and health of the men working under compressed air on the Queens Midtown Tunnel, as for the other features of this outstanding project. The experiences on the Queens Midtown Tunnel in this field have provided considerable important data which may help to establish improvements in methods affecting health, safety, and economy on future work.

As stated by the author, the medical record for work in compressed air on the Queens Midtown Tunnel shows great improvement over that of the East River tunnels of the Pennsylvania Railroad. These railroad tunnels were built at a time (1904–1908) when practical regulations for the prevention of compressed air illness were still in an experimental stage.[16] As shown in Fig. 2, the Queens Midtown Tunnel is located near the Pennsylvania Railroad tunnels, and, consequently, conditions encountered in construction were similar in many respects on the two projects. The comparison, denoting progress in the control of compressed air illness during the period from 1904 to 1939, is therefore a sound one, and the improvement shown is undoubtedly due to better regulations and better enforcement.

[15] Medical Consultant, New York City Tunnel Authority, New York, N. Y.

[16] "Caisson Disease and Its Prevention," by Henry Japp, *Transactions*, Am. Soc. C. E., Vol. 65 (1909), p. 1.

There were no legal regulations during the construction of the Pennsylvania Railroad tunnels. For gage pressures up to 32 lb per sq in., the working day was 8 hours long, with a half-hour rest period. For gage pressures of from 32 to 42 lb per sq in., there were two 3-hr work periods per day with a 3-hr rest period between them. An attempt was made to enforce a maximum decompression rate of 2 lb per min.

The first statutory regulations for work in compressed air to be adopted by New York State became effective on January 1, 1910. These have since been modified from time to time by reducing the hours of work. Projects constructed since 1925, including the 53d Street, Fulton, Rutgers-Jay, and Harlem River tunnels and part of the Holland Tunnel work, have been under the regulations shown in Table 3. The rest periods are ones actually adopted and are equal to or greater than the prescribed minimums.

The maximum rates of decompression required by these regulations are: For 0 to 15 lb per sq in., 3 lb per min; for 15 to 20 lb per sq in., 2 lb per min; for 20 to 30 lb per sq in., 3 lb per 2 min; and for 30 lb per sq in. or over, 1 lb per min. A stage method of decompression is used in which the pressure in "locking out" is dropped at a rapid rate (specified at 5 lb per min) to half the gage pressure, and the remaining decompression is at a uniform rate such that the total time of decompression, including that for the initial rapid drop in pressure, shall equal the time specified for the original maximum pressure.

The Queens Midtown and Lincoln tunnels both were built under these regulations with the modification that the schedule of 3 hours of work, 3 hours of rest, and 3 hours of work was adopted at 0 to 18 lb per sq in. as well as in the higher range from 18 to 26 lb per sq in. Also, on the Queens Midtown Tunnel, the decompression times in the higher pressures were increased in length from 2 to 8 min above those required by specified maximum rates.

TABLE 3.—REGULATIONS IN EFFECT IN THE STATE OF NEW YORK, GOVERNING THE MAXIMUM DAILY HOURS OF WORK PERMISSIBLE UNDER COMPRESSED AIR

Time sequence (hours)	GAGE PRESSURE, IN POUNDS PER SQUARE INCH						
	0–18	18–26	26–33	33–38	38–43	43–48	48–50
Work	4.0	3.0	2.0	1.5	1.0	0.75	0.5
Rest	0.5	3.0	4.0	4.5	6.0	5.25	7.0
Work	4.0	3.0	2.0	1.5	1.0	0.75	0.5

The Clark, Montague, 60th Street, and 14th Street tunnels were built under statutory regulations that permitted 8 hours of work in 24 hours in gage pressures of from 0 to 22 lb per sq in., two 3-hr work periods in from 22 to 30 lb per sq in., two 2-hr work periods in 30 to 35 lb per sq in., two 1.5-hr work periods in 35 to 40 lb per sq in., two 1-hr work periods in 40 to 45 lb per sq in., and two 0.75-hr work periods in 45 to 50 lb per sq in. Decompression was specified to be at the maximum rate of 3 lb per 2 min up to 36 lb per sq in., and 1 lb per min in pressures of 36 lb per sq in. and greater. Part of the Holland Tunnel work was performed under this schedule of hours of work with the exception that the first and second ranges of pressures were 0 to 21 and 21 to 30 lb per sq in., respectively.

It is noteworthy that there have been no deaths due to compressed air illness since the construction of the 60th Street tunnel, built from 1917 to 1921. In fact, the record shows quite conclusively that, although legislation is periodically demanded to further shorten the lengths of the working shifts, a practical limit already has been reached if not surpassed in this regard. Naturally it is to be expected that the shorter the time of exposure in compressed air the less the incidence of compressed air illness will be, but this can be carried to a point at which the cost of compressed air tunneling would be prohibitive. Although the practice, on the Queens Midtown Tunnel and other recently constructed tunnels, of limiting the working time to a maximum total of 6 hours in 24 hours is sound both from medical and operational standpoints, it is evident from the record that further reduction in the length of the working shift is not warranted.

Work under compressed air at the Queens Midtown Tunnel was supervised most carefully, and, in some cases, hourly limitations of work and decompression requirements were even more rigorous than required by the code. As stated by the author, working conditions and safety precautions were strictly in accordance with the best standard practice. There were almost three quarters of a million decompressions, most of them from pressures of from 26 to 37.5 lb per sq in. The reporting of cases of compressed air illness was encouraged and the records were kept carefully. It was the intention to approach the ideal as closely as possible. In this the Tunnel Authority had the full cooperation of the contractor and his staff, and also that of the members of the Compressed Air, Tunnel, Caisson, Subway, Cofferdam and Sewer Construction Workers Union.

Having in mind the idea of using oxygen while decompressing, so as to hurry the desaturation of the body fluids and tissues of excess nitrogen, the help of the Division of Industrial Hygiene of the National Institute of Health, U. S. Public Health Service, and U. S. Bureau of Mines was enlisted in a field study along these lines conducted from July, 1938, to May, 1939.

Theoretically, at least, this use of oxygen should have been successful. In conjunction with the investigation,[17] blood and urine tests were made on men who had suffered from attacks of compressed air illness, but no causative reason was found to show why these men should have been attacked while others, in whom there was no physiological difference, were not. Briefly, the tests with oxygen breathing were successful when conducted with smaller groups under the direct supervision of the representatives of the government agencies. When continued on a more extensive scale under the contractor's supervision, they were somewhat disappointing. The investigation indicated that the use of oxygen in decompressing would be practicable for the smaller groups of men, especially when they had been subjected to the higher pressures.

---

[17] "Administration of Pure Oxygen to Compressed Air Workers During Decompression," by R. R. Jones, J. W. Crosson, F. E. Griffith, R. R. Sayers, H. H. Schrenk, and Edward Levy, *Journal* of Industrial Hygiene and Toxicology, Vol. 22, No. 10, December, 1940, pp. 427–444.

As a by-product of the oxygen-breathing tests conducted on the Queens Midtown Tunnel work, the use of helium-oxygen mixtures for the alleviation of ear block was developed successfully.[18] As ear block is the cause of many compensation cases on compressed air work, as well as sometimes the cause of delay when a gang is locking into the tunnel, this use of a helium-oxygen mixture (for which a practical apparatus was perfected on the Queens Midtown Tunnel) is an important development.

It is interesting to note that on the Queens Midtown Tunnel work the onset of compressed air illness occurred in 38% of the cases during the first half hour after decompressing, 54% occurred during the first hour, 66% in the first hour and a half, and 72% during the first two hours after decompression. Corresponding percentages based on the record of a great number of cases on previous projects are, respectively, 44%, 64%, 73%, and 82%.

A comparison of the percentages of types of symptoms on the Queens Midtown Tunnel (A), the Pennsylvania Railroad East River tunnels (B), and 680 cases of compressed air illness in New York Public Service Commission Tunnel projects (C) is afforded by Table 4. These percentages are fairly consistent. As the joints, fibrous tissues, and fats of the body (which have poorer circulation than other parts of the body) desaturate more slowly during decompression, this accounts for the high percentage of symptoms which are classified as localized pain in the body.

TABLE 4.—INCIDENCE OF SYMPTOMS (PERCENTAGE OF TOTAL CASES)

Type of Symptom	A	B	C
Central nervous system	2.7	2.2	1.6
Localized pain in body	86.2	90.3	91.7
Vertigo	9.9	5.4	6.5
Chokes	1.0	1.6	0.1
Partial or complete unconsciousness, with collapse	0.2	0.5	0.1
Totals	100.0	100.0	100.0

A study of the blood of compressed air workers on the Queens Midtown Tunnel gave no clew to the susceptibility of some workers over others. However, there was a definite feeling that alcohol played a part in the occurrence of compressed air illness. Grover C. Emery, M.D., who was in direct medical charge of the contractor's employees has expressed this idea as related to dissipation following payday:[19] " '* * * a majority of cases occur following payday, and can be assumed to have dissipation as an etiological basis.' " However, there is no particular evidence, other than by casual observation, apparently, that there was an increase in dissipation following payday. Table 5 does show a marked increase in the incidence of compressed air illness after exposure on Sunday, which was covered by small watch shifts with little work to do. On the basis of such working conditions, a minimum incidence of compressed air illness would be expected rather than double the average incidence, as actually experienced. Could this phenomenon be due to the fact that Sunday follows Saturday night so closely?

TABLE 5.—INCIDENCE OF COMPRESSED AIR ILLNESS ON QUEENS MIDTOWN TUNNEL, BY DAYS OF THE WEEK (FOR 20 TO 37.5 LB PER SQ IN. GAGE PRESSURES)

Day	Total decompressions	Number of cases	Cases per 100 decompressions
Sunday (watch shifts)	15,715	64	0.407
Monday	90,303	112	0.124
Tuesday	100,567	177	0.176
Wednesday	100,239	194	0.194
Thursday (payday)	100,312	200	0.199
Friday	101,891	203	0.199
Saturday	99,637	193	0.194

The New York State regulations, under which the Queens Midtown Tunnel was constructed, provide that

> "Whenever the air pressure in a tunnel heading exceeds twenty-one pounds per sq. in. above atmospheric pressure, two air chambers shall always be in use, except for such time as may be necessary when headings are being started from shafts; and whenever practical the pressure in the outer chamber shall not exceed one-half the pressure in the heading."

This condition is established by constructing the necessary additional bulkhead and is generally worked out in conjunction with the maintenance of a bulkhead within a specified maximum distance of the heading, generally about 1,000 ft. Fig. 11A shows the location of the bulkheads forming the outer air chambers in the two Manhattan headings of the Queens Midtown Tunnel, and Fig. 11D shows the locations on the Queens side. Using the single bulkhead and no outer chambers, 270,672 decompressions were made from a 22 to 37.5 lb per sq in. range of pressure with 486 cases of compressed air illness, an incidence of 0.179 per 100 decompressions. Using the additional bulkheads and outer chambers, 316,595 decompressions were made from a 22 to 37.5 lb per sq in. range of pressures with 646 cases of compressed air illness, an incidence of 0.204 per 100 decompressions. As far as controlling compressed air illness is concerned, this record shows no advantage in the use of the outer air chambers; in fact, the record for the single air chamber is better. The use of the outer chamber has been looked on as a great aid in the prevention of compressed air illness but the results on the Queens Midtown Tunnel, comparing the aforementioned large number of decompressions, indicate that this may not be the case. As the cost of installation, operation, and removal of a tunnel bulkhead is a substantial one, further study of this regulation is advised as it appears that the use of an additional bulkhead solely to satisfy the requirement for an outer air chamber may be an unwarranted expense. This consideration, of course, is entirely apart from the use of additional tunnel bulkheads when necessary to satisfy other safety requirements.

In further regard to decompression regulations, exception could well be taken to the requirement that the stage method of decompression be used. Although there is nothing in the record of compressed air work in the New York area, including that of the Queens Midtown Tunnel, definitely to prove this assertion, there is, on the other hand, nothing to prove the efficacy of the stage method of decompression as far as tunnel work is concerned. In fact, it well may be that the fast initial drop of pressure employed in this method of decompression actually induces the beginning of the formation of the air bubbles that are the cause of compressed air illness. The initial drop to half the gage pressure, as practiced on the Queens Midtown Tunnel, was often slower than the rate of 5 lb per min required by the regulations. Nevertheless, it is possible that an even slower initial rate of decompression might have given better results. This should be investigated on the next compressed air tunnel project. It should be remembered that the stage method of decompression was developed in connection with diving, where the diver is raised slowly to the surface and is subject, meantime, to the low temperatures of the surrounding water. The stage method is designed to achieve what may be considered a safe decompression in the minimum time; and therefore it is a desirable method in deep water diving, for which it was developed, where the effect of cold increases the diver's susceptibility to compressed air illness. As tunnel workers decompress in a heated lock, a decompression method well may be used which sacrifices some small saving in time to greater safety.

It is interesting to note that, of the total of 1,148 cases of compressed air illness reported on the Queens Midtown Tunnel work, 194 or 16.8% occurred following the first of the two periods of daily exposure and that 954 cases or 83.2% occurred after the second period. Such a difference between the incidence of compressed air illness after the first and second periods of exposure may be explained in part by fatigue. The fact that some cases develop after the first period and are not reported until after the second (the men hoping to relieve themselves during the second exposure) may contribute slightly to the increased number of cases occurring after the second shift, but not to any great extent, as compressed air illness is painful and it is not likely many would wait several hours for relief.

In the lower pressures, especially up to 18 lb per sq in. and possibly higher, some consideration should be given to the use of one daily work shift of 6 hours, rather than two shifts of 3 hours. This modification would be in line with suggestions that have been made from time to time since the early days of the use of compressed air in construction, and the experience on the Queens Midtown Tunnel indicates that it might be practicable as there would be certain operational advantages without adverse effect on safety. This idea at least should receive further study.

Robert F. Legget,[20] **Assoc. M. Am. Soc. C. E.**—The literature of civil engineering has been enriched by this notable account of a notable undertaking, an account enlivened by attention to many unusual details of design and construction. As was to be expected for such a public work in the vicinity of New York, due attention was paid to the necessity for preliminary subsurface exploration. The costs of this work as given in Table 2, amounting to only 0.2% of the total contract cost, provide further evidence of the economic value of such exploratory work. The successful performance of the Queens Midtown Tunnel makes any discussion of the main parts of the paper of academic interest only. There are some details, however, that the writer would like to see amplified, if only briefly, and he therefore ventures to comment upon them.

(*a*) Under the heading "Design of Structures: Lining for Shield-Driven River Tunnels," the author gives some details of the fastening of the bolts used for securing the tunnel liner plates and it is noted that "Actual bolt stresses * * * varied from intensities considerably less than 25,000 lb per sq in. to stresses approaching the yield point of the bolts." Would Mr. Singstad advise whether the ratchet wrenches used for bolt tightening were merely standard wrenches or, alternatively, wrenches designed to give a fixed maximum torque? Use of wrenches of the latter type is standard practice in certain branches of aircraft work, great ingenuity having been displayed in their design. It is to be hoped that one of the many minor by-products of the present wartime industrial development will be the acceptance of such tools in civil engineering practice, particularly since bolts and turnbuckles form so important a part of many structures—being designed for definite initial stresses and yet all too often installed without reference to this requirement. The writer has in mind particularly the turnbuckles used for supporting bulkhead retaining walls as equivalent in importance to the bolts described in this paper.

(*b*) In dealing with the Manhattan plazas and approaches, the author states that one design for the plaza was not adopted since construction costs, for a thin invert slab and drainage system, were about the same as those for a very heavy slab design. This suggests that the drainage involved must have been unusually complicated. Could Mr. Singstad amplify this comparison of designs in order to make clear why drainage thus had to be neglected?

(*c*) Finally, in view of the "structural" use to which the clay in the river blanket was put, could Mr. Singstad give details of the type of clay used for the blanket, and also of the material referred to as "volcanic clay."

Orrin L. Brodie,[21] **M. Am. Soc. C. E.**—In his several allusions to the design of the Holland Tunnel, Mr. Singstad states that in all essential respects the design for the Queens Midtown Tunnel is the same design as that for the Holland Tunnel and that extended research is no longer necessary in planning and designing tunnels for highway traffic. The length of the cast-iron ring of the latter tunnel, after two decades, could be increased to 32 in., or 2 in.

---

[20] Asst. Prof., Dept. of Civ. Eng., The Univ. of Toronto, Toronto, Ont., Canada.

[21] Designing Engr., Board of Water Supply, New York, N. Y. (Mr. Brodie died on October 5, 1943).

over the earlier tunnel, thereby effecting considerable saving, while the number of segments (14) would remain unchanged. The initial bolt-tightening tension (25,000 lb per sq in.) is the same in the newer structure; but at the same time the author states (see heading, "Design: Lining for Shield-Driven River Tunnels") that "an allowance of about 5,000 lb per sq in. above the required bolt stress" is now made "to offset any plastic yield effect in the entire bolt assembly under sustained loading." From this statement the writer understands that 30,000 lb per sq in. is specified instead of the lower value.

Although the Holland Tunnel studies were based on a tube with an outside diameter of 29 ft, the sizes actually constructed were 29 ft 6 in. for the greater part and 30 ft 4 in. for a stretch in Jersey City in the northern tube, extending for 800 ft west of the New Jersey land shaft, to provide greater ventilation spaces and facilities for the long upgrade. This was the largest diameter shield-driven tunnel that ever had been constructed.

The author's statement that the operation of existing tunnels will continue to provide data for improvements in design is borne out in Table 1, which compares the ventilation of the Holland Tunnel with that of the Queens Tunnel.

The Holland Tunnel project presented problems unique in their time, both in design and ventilation, and called for pioneer work. It has been brought to the writer's attention, from several sources, that the studies for the Holland Tunnel have never been published. For this reason a report in January, 1921, to Mr. Singstad (who was then engineer of designs) on the studies for design of the Holland Tunnel ring is referred to herein. (The full report has been placed on file with Mr. Singstad's records for reference in Engineering Societies Library, New York, N. Y.) The conclusions still are applicable today to its prototype, the Queens Tunnel.

Analysis of Cast-Iron Tunnel Sections, Holland Tunnel.—Subaqueous shield-tunnel practice recognizes the uncertainty of absolute values of external loading, especially at the critical times during construction. A controlling consideration is the possibility of a state of collapse during construction rather than the realization of the safe working stresses that might be employed in direct designing.

Therefore, studies that are comparative are possible and were made on different sections of cast-iron tunnels, including sections proposed for the vehicular tunnel and sections of tunnels already built and in service under similar conditions. The various results were compared rationally through the different angles of repose (Rankine's theory) assumed for the material forming the bed of the Hudson River. The investigations included angles of repose ranging from 3° to 20°, which serve as an index common to all phases of the work, and also signify different relations of horizontal thrusts to vertical loadings, exterior to the tunnel.

The resultants of the forces acting on the tunnel lining include the weight of the tunnel ring and that of interior structural features together with compressed air within the tunnel and the exterior loads. The last named are least capable of precise definition; hence, varying the exterior forces throughout a comprehensive range yields more conclusive results than if attention is confined to any one set of forces, themselves of doubtful value. These exterior forces represent active thrusts based upon Rankine's theory of earth pressure. The horizontal, abutting resistances of the surrounding material could be developed only through the deformation of the tunnel ring. This deformation develops internal stresses, all predicated on the active thrusts. Stresses due to the active thrusts of the surrounding material at a given angle of repose may be found to equal the stresses due to the abutting power of the material at some other angle of repose. Therefore, for comparative purposes it should be sufficient to base these studies on active thrusts only and thus preclude the uncertainties of speculations as to what abutting resistances might be developed at a given angle of repose. At the same time conditions are approached that are admittedly more rigorous than those for the tunnel sections in their final state of completion, since the active thrusts provide a series of horizontal and vertical loads of increasing inequality that are more nearly representative of loads encountered during construction. Thus, in these studies comparative values are emphasized rather than any consideration of the forces assumed for the exterior loading at any given angle of repose.

Conclusions were drawn from comparisons of results which indicated the more favorable of alternative designs. Local points of weakness were developed and remedial measures were devised.

The analysis comprised the determination of true equilibrium polygons for different conditions of loading from which the resultant thrusts and bending moments in the tunnel rings were determined completely. From these thrusts and moments, the stresses in the cast iron were computed directly: First, by neglecting the effects of joints and bolts locally—that is, assuming a given ring to be continuous, acting alone, and with a cross section of corresponding segment design; and, second, by means of supplementary analysis, including the effect of the joints and bolts under stress. The results were plotted as curves, in terms of the angles of repose, in both cases, and conclusions were made.

The true equilibrium polygons were determined by the method of work and the method of deflections. The advantage of the latter method is that it makes graphics unnecessary, and thereby is more precise than the natural limitations of graphical analysis. The method of work, as applied herein, consists of a graphical adaptation of the principle of least work, and, although generally satisfactory for ordinary purposes, lacks sufficient precision for low angles of repose, where percentage errors in scaling thrust eccentricities increased. Wherever both methods were used, the deflection method checked back most accurately on results found independently by employing the principle of least work.

Supplementary analysis of the action of the bolts under stress and the modifications of resulting stress in the cast iron of the segments were made. In general, the joint and bolt analysis consisted of investigations of (1) the modifications of stress sustained by the cast iron caused by the action of the bolts in the end and circumferential flanges of a segment and, through the bolts in the latter, (2) the effect of the two adjacent rings on the given ring between them. The elasticity of the bolts, the bending of the short longitudinal flanges of the tunnel ring, the transfer of compression from the joint to the body of the segment, the tendency of a joint to open, and the friction between the circumferential flanges enter this part of the investigations. These calculations of bolt and joint stresses are also dependent upon the true equilibrium polygons, determined previously.

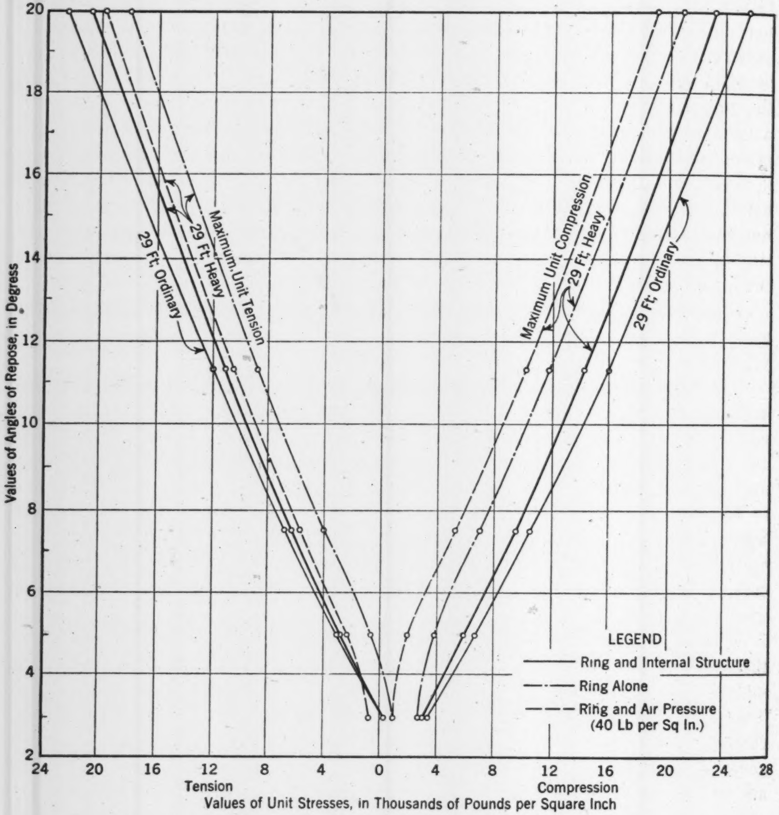

FIG. 15.—COMPARATIVE STRESSES, CAST-IRON RINGS OF THE HOLLAND TUNNEL

The effect on the bending moments of the ring manifested by horizontal ties at the roof and floor of the driveway of the vehicular tunnel, 29 ft in diameter, was also approximated.

The cast-iron ring with entire internal structure, the cast-iron ring alone, and the cast-iron ring subjected to compressed air within furnished three distinct cases for investigation. The concrete lining was considered only as contributing its dead weight.

The basis of computation was 1 ft of tunnel length; 38 ft of water on 31 ft of silt were assumed to rest on the top of the tunnel ring. The weights of water and silt were assumed, respectively, at 64 lb per cu ft and 104 lb per cu ft. The air pressure, for the 29-ft tunnel, was applied at 40 lb per sq in.

As cohesion is neglected in Rankine's theory of a "granular mass," vertical forces due to tunnel ring alone, and to the overlying material, in some cases are less than the upward active pressures computed according to this theory. In such cases it appears that the structure would tend to float. For the sake of equilibrium the vertical forces are equalized by adding the necessary difference as a uniform, overlying load, which may be considered either as due to extra fill or as a tacit recognition of the existence of cohesion in the overlying mass. During the construction of the Holland Tunnel the characteristics of

the silt were found and its value in cohesive effect fully determined. The overlying depth of silt at one place, for the tunnel, showed no tendency to float although its buoyancy, in terms of simple displacement of water and silt, indicated otherwise. Similarly, where the downward forces exceed the upward active pressures, the uniformly distributed difference required to balance is applied on the lower half of the structure. This additional set of forces may be considered as a partial development of the vertical abutting resistance of the material below the tunnel. In this case, the resulting upward reaction is found to lie between the values of the forces derived from the active pressures and those that would result if the full abutting pressures could be developed, according to the theory. The assumed elastic limits were 40,000 lb per sq in. for steel bolts and 80,000 lb per sq in. for alloy ("high tensile") steel bolts. In all cases the stresses were computed for the so-called "heavy" section of segment, except for the stresses shown in Fig. 15, for the complete structure of the "ordinary" section of 29-ft tunnel. The web thickness of the heavy section was 2 in.; that of the ordinary section, $1\frac{7}{8}$ in.; and that of the final design for the Holland Tunnel, $1\frac{5}{8}$ in. However, the extent of the web thickening for the heavy section was 7 in. back from the inside corner of the flange, instead of the 6 in. of the studied, ordinary sections. The equilibrium or funicular polygons were derived for the "ordinary" section of the 29-ft tunnel, and the stresses calculated for the "heavy" section were based on these polygons as the differ-

ence between these two sections was such as to affect inappreciably—a small fraction of 1%—the resulting bending moments and thrusts.

Discussion of Analysis.—In the following, the terms "outer," "inner," "outside," and "within" refer to directions in the circular tunnel cross section from or toward its center, respectively.

Eight features of the analysis deserve comment in so far as they apply to a similar analysis of the Queens Midtown Tunnel: (1) Application of thrust; (2) the joints; (3) location of critical stress; (4) bolt tightening; (5) location of end flange bolts; (6) the nonutility of the middle end flange bolt; (7) flange thickening at corners and the web of the section; and (8) effect of tie rods.

(1) Inspection of the funicular polygons used in the analysis indicated that the thrusts in the ring may be outside or within the neutral axis of the ring—that is, positive or negative bending moments, besides direct thrusts in the ring may exist. Two cases thus may arise—Case I, with thrust outside, and Case II with thrust within, the neutral axis. The calculations showed that Case I resulted in maximum stresses in tension and Case II, in maximum stresses in compression; hence, Case I usually governs.

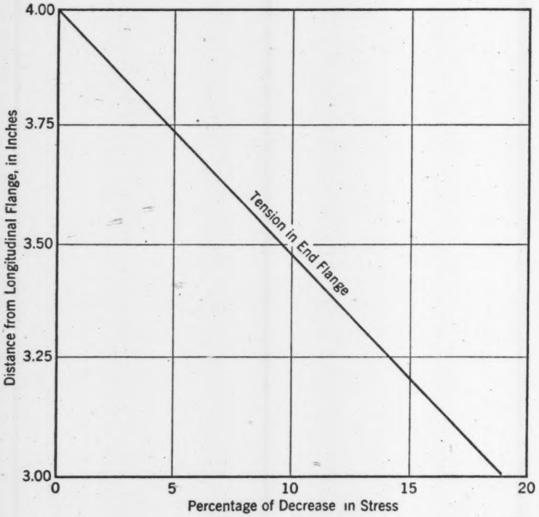

Fig. 19.—Percentage Stress Variation with Change in Bolt Position (Bolts Assumed Stressed to 40 Kips per Sq. In., the Elastic Limit, at Beginning)

(2) The joint, as may be expected, is the weakest feature of the tunnel ring. Comparison of the stresses in the 29-ft, cast-iron-segment, heavy-section, preliminary design, with those for the same section, but with joints neglected, indicates the increase in stress due to the joints. Hence, to strengthen the ring as a whole, it is necessary to increase the strength of holding at the joints.

In Fig. 15, only the cast-iron segments are assumed to withstand stresses, and the effects of joints and adjacent rings are neglected. In Fig. 16, on the other hand, the effects of bolts and joints are considered. The bolts are assumed to be stressed to the elastic limit at the beginning, and the maximum tension at the joint occurs in the segment near the end flange.

SECTION *A-A*

END FLANGE OF SEGMENT

FIG. 20.—STRESS CONDITIONS WITH THE CENTER OF PRESSURE NEAR THE EXTRADOS (CASE I)

(3) The critical stress in a segment is not in the joint itself, but immediately adjacent to it, at the intersection of the circumferential flange of the tunnel ring. This stress is due to the combination of the normal bending stress in the body of the segment, as this bending is modified by the circumferential bolt action, with the stress resulting from the local bending induced by the bolts of the end flange. These last bolts bind together the two successive segments of a ring at their ends.

(4) The tighter a joint is bolted, the greater the strength of that joint, and consequently, the ring. Fig. 17 indicates that the greater the stress which the bolts can carry, as initial stress (that is, in bolting operations) the greater the strength of the ring will be. Although a small increase in tension is apparent (due mainly to the circumferential bolts) in the body of the segment, where the tensions are usually lower than at the joints, this is inconsiderable when compared with the great decrease in stress in the critical part of the segment, the end flange, where the stresses are much higher. Fig. 16 shows a similar effect obtained by utilizing the higher elastic limit of alloy steel bolts of 1¾-in. diameter, instead of that of ordinary steel. The importance of keeping all bolts tightened constantly to their utmost strength, especially during construction when the tunnel ring receives its greatest punishment, is evident from these results alone and suggests the desirability of bolt tightening by means other than manual, if possible. Finally, the advantage of changing to the 1¾-in. alloy steel bolts is obvious. Fig. 18 shows this design.

(5) The nearer the outer two bolts in the end flange of a "plate," or segment, approach the web and the nearer the two side bolts of the inner three approach the circumferential flanges, the greater will be the reduction of local bending stresses, along with compression in the joint induced in the metal at the joint. Fig. 19 indicates the reduction in the case of the inner bolts.

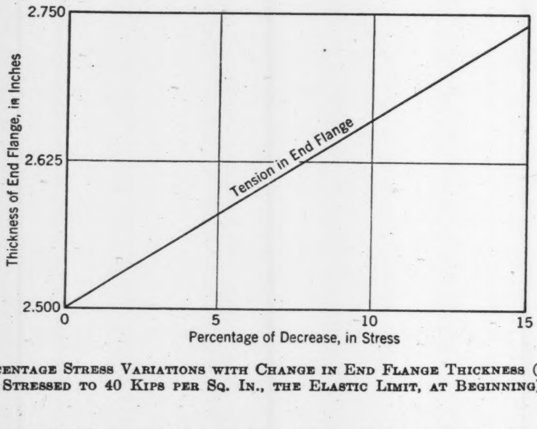

FIG. 21.—PERCENTAGE STRESS VARIATIONS WITH CHANGE IN END FLANGE THICKNESS (BOLTS ASSUMED STRESSED TO 40 KIPS PER SQ. IN., THE ELASTIC LIMIT, AT BEGINNING)

(6) The middle of the three inner bolts of the end flange (Fig. 18, Section A–A) cannot act with its two adjacent bolts, for, if the elasticity of the metal of

the bolts and joints is considered at all, and the elastic deformations are the essence of the studies, the action of the two inner bolts adjacent to this middle bolt puts the middle part of the end flanges of the two abutting segments meeting at this joint into compression. No possibility was found of a tension being induced in this bolt, except that caused by bolt tightening, unless the other bolts were stressed to failure, a condition that the middle bolt never could withstand. The only apparent advantage is the aid of the middle bolt in the process of tightening the remaining bolts—a practical consideration only. It is plainly easier to tighten up three bolts in line successively, back and forth, than two bolts alternately. As a factor contributing to tunnel-ring strength the value of the middle bolt is nil. This conclusion resulted from the analysis of bolt and joint stresses but may be suggested by regarding the cross section of such a segment as Section A–A of Fig. 18 along with Section A–A of Fig. 20.

(7) To strengthen the segment locally (Conclusion 2) it was further concluded that the metal of the flanges, inside, at the corners of the segment should be thickened as shown in the side view of Fig. 18. The comparative value of this local flange thickening is brought out in Fig. 21, where the end flange is thickened $\frac{1}{4}$ in. Subsequently, when the tunnel segments were being cast, it developed that this combined thickening at the corners resulted in better castings, since the casting with more metal than heretofore cooled at the corners so that a more uniform texture of metal was indicated as observed upon castings which were purposely broken for inspection.

(8) In addition, a study of the restraining effect of transverse tie rods in the roof and floor systems indicated that they would provide for a reduction of two thirds in the values of the maximum bending moments in the ring.

A. A. Eremin,[22] Assoc. M. Am. Soc. C. E.—Interesting details of design and construction for the Queens midtown subaqueous tunnel have been presented in this paper. In the "Conclusions" the author has stated that "Extended research is no longer necessary in planning and designing tunnels for highway traffic, * * *." Although it is true that considerable improvement in design and construction of subaqueous tunnels has occurred in the last two decades, further study is necessary.

Method of Construction.—It is well known that in tunneling soft ground shield driving is the most economic method. The protective blanket is generally used to prevent excessive loss of air and blowout accidents although the mechanical properties of the blanket assuring safety are still not definitely determined. On account of defects in the protective blanket, a serious blowout accident occurred during the construction of the Holland Tunnel. As a result, an improved type of blanket was used in the East Boston Tunnel, which, nevertheless, suffered considerable loss of air through the pile holes at the pierhead line. Similarly, much air was lost during construction of the Queens Midtown Tunnel, as reported by Mr. Singstad.

---

[22] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

The Posey Tunnel penetrating soft ground between Oakland and Alameda, Calif., although designed almost at the same time as the Holland Tunnel, was constructed by open-trench excavation and by floating pre-cast concrete segments. The shield-driving method was rejected because of the excessive cost of protective blanket.

Shield driving has many advantages, as has been pointed out in this paper:

(1) It causes very little disturbance in the ground. This is especially important because subaqueous tunnels are generally constructed at highly developed sites, and slight disturbance in the ground permits construction of twin tunnels close together. The Queens Midtown tunnels were 45 ft apart. Similar spacing of twin tunnels proved safe in driving the Holland and Lincoln tunnels.

(2) It may often result in saving of construction time. The speed of driving for the Queens Midtown tunnels was about 7.4 ft per day. The Lincoln tunnels were driven at the even higher rate of 45 ft per day.[23] Nevertheless, because it is an essential part of shield driving, further study of the mechanical properties of the protective blanket is highly desirable.

Loading.—An extensive study of loading on the subaqueous tunnel lining was made for the design of the Holland and Posey tunnels. As a result of this research, a circular rigid tube with steel ties at the roadway slab and ceiling was adopted for lining tunnels. During the construction of the Posey Tunnel at some sections the tie rods at the roadway slab were under compression instead of tension. The horizontal diameter was shortened during construction of the Lincoln Tunnel.[23] In the Queens Midtown Tunnel a flattening effect in the heavy cast-iron lining was observed, thus confirming the original study of loading. Mr. Singstad has shown important effects of grouting on distribution of loading and increasing resistance of the ground to the air losses. However, he states that (see heading, "Construction: River Tunnels") "The heading was dewatered on August 8, 1938, disclosing an inflow of grout and muck at a maximum depth of 14 ft at the shield and running back a distance of 208 ft in the tunnel." Thus, in shield driving, a further study of the methods of grouting is still essential. Correct grouting may control the load on the lining and the rate of shield driving as stated in the paper.

In the shield-driven tunnels various types of lining have been used. The most well-known linings are cast-iron, structural steel plate, and concrete. Mr. Singstad states that (see heading, "Design of Structures: Lining for Shield-Driven River Tunnels") "Cast-iron lining of the usual design was chosen for the shield-driven tunnels as best adapted to resist shield thrusts and to provide rigidity and watertightness" and that "* * * lack of uniformity in stress, may contribute to some leakage, * * *." The cast-iron segments have been proved rigid. However, their rigidity is decreased at the connections. Fig. 3 shows that the bolt holes in the segments are $\frac{1}{4}$ in. larger than the bolts. Evidently with such clearance pre-stressing and the use of a high strength steel for the bolts cannot make the connections as rigid as the segment units. Sufficient

---

[23] *Engineering News-Record*, June 24, 1937, p. 955.

rigidity and watertightness in the lining of the Lincoln and Detroit tunnels were obtained with the structural plate segments, which are generally three times lighter than cast-iron segments. To resist the direct thrust from the shield the structural plate liners generally are reinforced with old rails or H-sections.

Ventilation.—When the Holland Tunnel was being designed, very little was known about the ventilation of vehicular tunnels. In cooperation with the U. S. Bureau of Mines, formulas for the design of ventilation features in the tunnels were developed. Poisonous gas, carbon monoxide, was limited to 4 parts per 10,000. After the construction of the Holland Tunnel tests revealed that during maximum traffic the amount of carbon monoxide never was more than 1.60 parts per 10,000.[24] At first it was concluded that the Holland Tunnel and the Posey Tunnel (which was designed on a similar principle) were overequipped. However, it was decided later that greater circulation of fresh air purifies the odor and smoke resulting from combustion of oil in the vehicles. Nevertheless, in subsequent tunnels and in the Queens Midtown Tunnel, design of ventilation facilities was based on a limitation of the maximum amount of carbon monoxide. Evidently the physical properties of smoke and burned oil are different from those of the vitiated air containing carbon monoxide. Therefore, for an economic ventilation design, further study of the smoke problem is necessary. Separate fresh air outlets were used in the Broadway Tunnel in Berkeley, Calif. It is quite possible that the separate openings may require a greater air pressure at the bulkhead. For efficient design of ventilation a minimum loss of air pressure at the ventilating fans and at the outlets near the bulkhead is essential.

Transition of Light.—Various methods of lighting at the portals have been used to eliminate the discomfort and the blinding effect of daylight. It is interesting to determine the various possible structural details for regulating light. Mr. Singstad has shown that the belled-out approach structure provided a gradual transition of light. In the Broadway Tunnel in Berkeley, transition of light was improved with transparent roofing between the approach retaining walls.

Conclusions.—Vehicular tunnels have an important rôle in solving problems of growing interurban traffic. Therefore, the author should be highly commended for presenting such interesting information on the design and construction of the Queens Midtown Tunnel.

ARTHUR S. TUTTLE,[25] PAST-PRESIDENT AND HON. M. AM. SOC. C. E.—Essential data concerning the Queens tunnel project, with very complete information as to its inception, administration, design, construction, and cost are recorded in this paper. The profession is indebted to Mr. Singstad for making this information available not only as a matter of historical interest but also as a help in the planning of structures of similar character.

As is generally the case with all monumental projects undertaken by the City of New York, many years elapse between the need for such a facility and the completion of the final plan, during which period various pros and cons are given consideration, all of which must be appraised. The possibility of securing federal aid in 1936 was doubtless responsible for the city committing itself definitely to the project at that time. The 30% grant, with a 70% loan offered by the PWA, for meeting the entire cost of the project, was conditioned upon the presentation of evidence that the project was necessary and would be self-supporting and that construction would be begun without delay. The former condition was intended to insure against wasteful expenditures; and the latter, to relieve unemployment in accordance with the primary purposes of the congressional act under which the PWA was set up and provided with funds.

[24] *Engineering News-Record,* June 9, 1927, p. 934.

[25] Cons. Engr. (Tuttle, Seelye, Place & Raymond), New York, N. Y.

The tunnel is located between the nonrevenue producing Williamburg and Queensborough bridges, both of which are badly congested during hours of maximum traffic. Extensive traffic studies were presented by the Tunnel Authority to support the claim that the relief to the bridge traffic which would be afforded by the tunnel would bring enough business to justify the project as financially sound. These studies contemplated the provision, by the city, of adequate highway approaches in the Borough of Manhattan and the Borough of Queens, which were considered essential to the successful operation of the tunnel. Had the cost of these approaches been included in the project, it is more than likely that the project would have been disqualified for a loan on the ground that it would not be self-supporting.

Although plans have been developed for a much needed crosstown tunnel in Manhattan to relieve the narrow and congested streets, overworked by traffic destined for the west side and for New Jersey, no definite commitment has yet been made. In the Borough of Queens a part of the approach system has been constructed, but major links are still lacking. Until adequate feeders are provided, the traffic capacity of the tunnel will not be fully utilized, and revenues will be handicapped.

When the project was finally accepted by the PWA as a part of its program and the "go-ahead" signal was given to the Tunnel Authority, difficulties began to develop: State legislation was threatened which would substitute a bridge instead of a tunnel; civil service procedure for a time raised barriers to the selection of an engineering staff properly qualified for the work; and rapidly rising prices for labor and material occasioned a question as to the sufficiency of the available funds. Pending the solution of these difficulties, the federal government threatened to withdraw the loan and grant so that the funds could be diverted to projects which could be put under construction more speedily. During all of this troublous period, there was very close cooperation between the engineering staff of the Tunnel Authority and the engineering staff of PWA, the final outcome being a commitment to the river crossing, which necessarily placed the project on a list from which there could be no withdrawal.

The tunnel, as completed, undoubtedly represents the latest and best of engineering skill in subaqueous tunnel construction, and the author is to be complimented for his success in overcoming the many obstacles placed in his way as the project advanced.

Ole Singstad,[26] M. Am. Soc. C. E.—The discussions, and the questions raised in them, have contributed much to the value of the paper. The writer appreciates the complimentary remarks regarding the paper made by the discussers, and he is particularly gratified that no less than six of his former associates in the planning and building of the Holland Tunnel have taken part in the discussion.

Mr. Fluhr relates the fundamental differences between the geology of the East River and that of the Hudson River, describing the causes of the variations in character of rock and the porous nature of the overburden in the East River which account for the increased hazard, slower progress, and higher cost of building a tunnel under the East River as compared to the Hudson River.

Mr. King suggests an interesting experiment to determine whether a soft plastic backfill such as clay, with perhaps a small admixture of bentonite outside of the tunnel lining in rock, instead of grout and gravel, would make the lining more nearly watertight. If practicable, this would undoubtedly be an aid to the watertightness of the tunnel. This kind of fill, however, would greatly reduce the passive lateral support of the surrounding material. The light cast-iron lining is designed to withstand, in addition to the hydrostatic pressure, a load of 10 ft of loose rock above the top of the tunnel, assuming full support at the haunches by grout and gravel. If this full support is removed and a plastic material substituted under this loading condition, excessive tensile stresses and deflections are indicated. To meet such a contingency, permanent blocking or supports might be constructed between the outside of the lining and the rock as required, although this would not always be practicable.

Mr. Wagner makes an analysis of the operating costs of the Queens compressor plant of the Queens Midtown Tunnel. The observation is made that it is the fixed charges that are important in considering construction power-house costs and that savings made in them are of more importance than economies in operating expenses.

The tunnel engineer's chief responsibilities with regard to the power house are (1) to provide a compressor plant of sufficient low-pressure air capacity to be adequate for the worst conditions anticipated, and (2) to assure continuous operation. Economy of fixed costs and operating costs must be considered, but it is of secondary importance to these requirements. An experienced tunnel engineer may be able to make a reasonable estimate of the required average compressed air capacity of a proposed plant, but such a capacity would generally not be safe to install.

The low-pressure air capacities specified for the Queens Midtown Tunnel were determined primarily on the basis of the experiences during construction of the Pennsylvania Railroad Tunnels, which had been constructed near-by through somewhat the same materials as the Queens Midtown Tunnel. Even with this basis of comparison it was difficult to anticipate the Queens Midtown Tunnel requirements, as its diameter (31 ft) differed considerably from that of the Pennsylvania Railroad Tunnels (23 ft). To insure continuous operation, three independent power sources were provided for each compressor plant of the Queens Midtown Tunnel.

---

[26] Chf. Engr., New York City Tunnel Authority, New York, N. Y.

Actual experience in driving the Queens Midtown Tunnel demonstrated that the low-pressure air capacity provided on the Manhattan side was none too great, whereas the low-pressure air capacity of the plant on the Queens side might have been made less without jeopardizing the work. The writer cannot

TABLE 6.—COMPARISON OF COSTS AND CONSTRUCTION INDEXES

Item No.	Description	Holland Tunnel	Lincoln Tunnel		Queens Midtown Tunnel
			South tube	North tube	
	Contracts let	1922	1934	1937	1937
	(a) CAST-IRON LINED SHIELD-DRIVEN TUNNEL				
1	Dollars per linear foot	1,430	1,235	1,657	3,159[a]
2	Dollars per cubic foot	1.83	1.63	2.20	4.18
3	Percentage cost per cubic foot	100	89	120	228
	(b) BASIC LABOR RATES				
4	Muckers, dollars per day	7.00	10.00	11.00	11.00
5	Ironmen, dollars per day	8.00	10.00	11.00	11.00
6	Miners, dollars per day	8.50	11.00	12.00	12.00
7	Average, all sandhogs	8.00	10.50	11.50	11.50
8	Index number (Holland Tunnel, 100)	100	131	144	144
9	Tunnel laborer, dollars per hour	0.60	0.75	0.825	0.825
10	Form setter, dollars per hour	1.125	1.40	1.40	1.40
11	Average, cleaning and concreting (Items 9 and 10)	0.862	1.07	1.11	1.11
12	Index number (Holland Tunnel, 100)	100	125	129	129
	(c) BASIC MATERIALS				
13	Cement, in dollars per barrel[b]	2.43	2.48	2.07	2.07
14	Steel shapes, in dollars per hundred weight	1.70	1.78	2.21	2.21
15	Cast-iron lining, in dollars per ton delivered	35.00	56.80	61.20	60.70
	(d) INDEX NUMBERS, ENGINEERING NEWS-RECORD				
16	Construction cost (1913 = 100)	174.45	198.10	234.71	234.71
17	Construction cost (1922 = 100)	100	113	140	140
18	Materials cost (part of Item 16)	79	88	103	103
19	Materials cost (1922 = 100)	100	111.5	130.6	130.6
	(e) AVERAGE LABOR WAGE, NEW YORK CITY				
	Skilled Labor:				
20	Dollars per hour	1.17	1.52	1.71	1 71
21	Index number (1922 = 100)	100	130	146	146
	Common Labor:				
22	Dollars per hour	0.60	0.8475	0.76	0.76
23	Index number (1922 = 100)	100	141	127	127
	(f) TUNNEL COST INDEXES (HOLLAND TUNNEL = 100)				
24	Labor only	100	130	141	141
25	Material only	100	156	166	164
26	Labor and material	100	143	153.5	152.5

[a] The contractor's payrolls aggregated $1,287 per foot of cast-iron lined shield-driven tube, exclusive of shafts and including concrete lining placed under river contract on the Queens Midtown Tunnel, or as much per linear foot as the total cost of the same work on the south tube of the Lincoln Tunnel. [b] Delivered in New York City.

agree with Mr. Wagner's statement, however, that the "Queens side of this tunnel was in exceptionally good ground for tunneling," although the ground was much better than that encountered on the Manhattan side and generally somewhat better than had been anticipated. Most of the large-diameter, shield-driven tunnels constructed prior to the Queens Midtown Tunnel had been driven in what could correctly be described as exceptionally good ground for tunneling, consisting largely of impervious silt and clay, vastly superior for tunneling to the ground encountered on the Queens side of the Queens Midtown Tunnel. Among these tunnels the writer would include the Holland, Lincoln, East Boston, and Antwerp tunnels and the shield-driven sections of the Detroit-Windsor vehicular tunnel.

Predetermination of the required capacity of a compressor plant to meet exactly the low-pressure compressed air requirements is practically impossible, especially for a tunnel diameter as large as that of the Queens Midtown Tunnel and with similar ground conditions. The tunnel engineer's judgment, in determining the proper capacity to be installed, must be guided by considerations of a margin of safety to meet emergencies which are more important than the fixed and operating costs.

Colonel Wilgus raises several pertinent questions. The quantity of leakage during winter months is too small to be measured, and during the summer there is no evidence of any leakage. The objection to such a small amount of leakage in the tile-finished interior of a modern vehicular tunnel is largely, if not entirely, on the basis of appearance.

The estimated cost of the Queens Midtown Tunnel compared with the actual cost is the estimate made at the outset by the writer when acting as consulting engineer to the Tunnel Authority before the engineering staff was organized. It was based on preliminary plans and made at the time of application to the PWA for funds for the project.

The cost per linear foot of cast-iron lined shield-driven tunnel, exclusive of shafts and including concrete lining as placed on the river contracts, is given in Item 1, Table 6(*a*), for the Holland Tunnel, as of 1922, the south tube of the Lincoln Tunnel, as of 1934, the north tube of the Lincoln Tunnel, as of 1937, and the Queens Midtown Tunnel, as of 1937. The respective costs per cubic foot of tunnel are given in Item 2 and, on the basis of 100% for the Holland Tunnel, the respective percentage costs are given in Item 3, Table 6(*a*).

The index numbers in Table 6(*f*) are based, for material (Item 25), on the cost of cast-iron lining (Item 15, Table 6(*c*)) and concrete per cubic foot of tunnel and, for labor (Item 24), on the basic labor rates for sandhogs (Item 7, Table 6(*b*)) and for the labor used in cleaning the tunnel and concreting (Item 11). Using the index numbers in Item 26, Table 6(*f*), the costs of the Queens Midtown Tunnel, reduced to Holland Tunnel conditions (1922), were as follows:

	Dollars per cubic foot (Holland Tunnel basis)	Percentage comparison (1922 = 100)
Holland Tunnel	1.83	100
Lincoln Tunnel, south tube	1.135	62
Lincoln Tunnel, north tube	1.43	78
Queens Midtown Tunnel	2.74	150

In other words, if contracted for under labor and material rates prevailing at the time of the construction of the Holland Tunnel, the river section of the south tube of the Lincoln Tunnel would have cost 62% as much as the Holland Tunnel per unit, that of the north tube of the Lincoln Tunnel 78%, and that of the Queens Midtown Tunnel 150%.

It should be noted that these differences in cost, as adjusted for the labor and materials indexes, are applied to the shield-driven river sections only and can be accounted for practically in their entirety on the following basis:

The Holland and Lincoln tubes were constructed through substantially the same kind of material, namely, Hudson River silt. As the Holland Tunnel was the first large tunnel built under the Hudson River, there was much uncertainty as to the behavior and stability of such a large tunnel in this soft material during the construction period. Therefore, the bid prices were high, but in view of the uncertainties, not unduly high. During the driving of the Holland Tunnel, after considerable experimentation, it was found that only about 20% of the material displaced by the tunnel had to be taken in through the face of the shield, and approximately 80% could be pushed aside by advancing the shield through the silt. This had two distinct advantages—namely, fast progress with correspondingly reduced cost, and stability. It was found that by leaving the 20% of the displaced material in the bottom of the tunnel until shield driving was completed, the weight increased the stability of the tube which, during the disturbed condition attending the shield driving, had a buoyant tendency. When the south tube of the Lincoln Tunnel was being built, this exploratory or pioneering work on the Holland Tunnel was used to great advantage by the contractor in adapting his tunneling methods from the start to the experience gained on the former project. The contractor's manager-engineer on the Lincoln Tunnel was a former resident engineer in charge of building the Holland tube on the staff of the chief engineer of the Tunnel Commissions. In the building of the Lincoln Tunnel the contractor developed a mechanical bolt-tightening device which greatly increased progress, since no muck was transported out of the tunnel until after the tube construction was completed. The progress was then a function of the speed with which the iron rings could be erected and bolted together. If another similar tunnel in material such as Hudson River silt were to be built by experienced tunnel engineers and contractors, the cost of the under-river section of the Lincoln Tunnel south tube would be a truer basis for cost estimating than that of the Holland Tunnel.

In the case of the Queens Midtown Tunnel, which is the last one to be built, the cost as adjusted for the labor and material index (Item 26, Table 6(*f*)) is very much in excess of that of either of the Hudson River tunnels, and this can be ascribed in its entirety to the extremely difficult and hazardous ground conditions existing on a great part of the Queens Midtown Tunnel site, which impeded progress and caused higher air pressures, with correspondingly reduced daily working hours for labor with increased daily rates.

The contract for the north tube of the Lincoln Tunnel was let under approximately the same labor and material cost conditions as the Queens Midtown Tunnel shield-driven section. The fact that this tube was driven alongside the already completed south tube accounts for its higher adjusted cost as compared with the south tube.

Mr. Thoresen states that careful thought has been given to providing the traveling public with an "attractively finished, well lighted, pleasant, and comfortably ventilated subaqueous highway." The writer has long been an advocate of this kind of treatment of vehicular tunnel projects, as reflected in the development of the use of a tile finish on the walls of the Holland Tunnel. At the time of the building of that tunnel, no tile was manufactured in the United States which was deemed suitable for the severe moisture and temperature conditions that would prevail in a tunnel in this climate, and an extensive research program was conducted with the assistance of the late George H. Brown, professor and head of the Department of Ceramics at Rutgers University, New Brunswick, N. J. Extensive laboratory and field tests were made on a large number of tile samples manufactured in the United States and abroad. This resulted in specifications which produced a wall tile not only pleasing in appearance but easy to clean and durable. One half of the tile used on the walls of the Holland Tunnel was imported and the other half was manufactured in the United States. The research work on tile and the requirements specified for the Holland Tunnel have stimulated the domestic tile industry so that this high quality tile is now considered a standard product.

The trench and pre-cast type of tunnel design and construction, on a scale larger than any heretofore undertaken, is contemplated for the Narrows Tunnel between Brooklyn and Staten Island, where conditions indicate that this method is both practicable and economical.

Both Mr. Cruthers and Mr. Geenens correctly state some of the reasons for the greater economy in the operation of the Queens Midtown Tunnel as compared to the Holland Tunnel.

Mr. Conover very appropriately emphasizes the point that the Queens Midtown Tunnel is merely one link in an east-west express highway route running through mid-Manhattan and extending far out on Long Island and into the State of New Jersey. From its very inception, in 1926, all those who had made a comprehensive study of traffic conditions in the metropolitan area realized the necessity for such a through highway. This route comes under many jurisdictions—the state highway departments of the two states, the parkway authorities, the borough presidents of the various boroughs, the Department of Public Works of the City of New York, and the two authorities charged with the responsibility of financing and building the river crossings.

Although, as of 1944, the two principal links in this route—the Lincoln Tunnel under the Hudson River and the Queens Midtown Tunnel under the East River—have been in operation for a period of six and three years, respectively, very little else has been done to complete this through route. In fact, only about two miles of modern highway have been built—namely, that part immediately east of the Queens plaza of the Queens Midtown Tunnel which was completed by the City of New York simultaneously with the opening of that tunnel.

Mr. Conover expresses the hope that the New York City authorities will include a crosstown tunnel connecting the two river tunnels as a postwar project. The writer is in accord with this hope. It would be a rational development of the city's highway system. Other missing links in this through route, particularly extensions farther out on Long Island, should be included.

During the past decade, 1933–1943, New York City has been preoccupied with the building of parkways and high-speed roads for the exclusive use of "pleasure" traffic; that is, passenger cars. Commercial vehicles of every kind have been excluded. Scores of millions of dollars have been spent for this type of highway, with the result that there has not been enough money left to provide modern highway facilities for business traffic. Commercial traffic is still shackled with the stop-and-go lights almost as much as it was twenty years ago. It may have been assumed by those responsible for this policy that, by removing a large amount of passenger cars from the streets and placing them on express highways, there would be that much more room for commercial traffic on the streets with the stop-and-go lights. Experience has demonstrated, however, that this is only partly true because, with the new facilities for the fast movement of passenger cars, there is also a corresponding increase in "pleasure" driving. It is to be hoped that much more attention will be given in New York City to high-speed roads for mixed traffic than has heretofore been the case; otherwise the increased cost of doing business here due to traffic delays is certain to have adverse effects.

Mr. Conover refers to the West Side Plaza and the East Side Plaza developed for the Midtown Manhattan Tunnel by cooperation, in the first case by the engineers of the Board of Transportation and those of the Port of New York Authority, and in the second case by the engineers of the Board of Transportation and those of the Borough President of Manhattan. He states that the East Side Plaza adopted by the New York City Tunnel Authority differs radically from the plan developed by the Board of Transportation. This is also true of the West Side Plaza. The plan developed jointly by the engineers of the Port Authority and the Board of Transportation and recommended for adoption in April, 1931, by the chief engineer of the Port Authority located the four exits and entrances of the twin Hudson River tubes and of the Manhattan tubes on the easterly line of 10th Avenue in the two narrow blocks between 37th and 39th streets. The writer, who at that time (1931) was one of several consulting engineers to the Port Authority, after analyzing that plan, pointed out that such an arrangement would create unsatisfactory traffic conditions, with resultant congestion and confusion on the four tunnel approaches as well as on the adjacent city streets, particularly on 10th Avenue. The plan violated what the writer considers a fundamental principle—namely, that eastbound traffic and westbound traffic should be separated as much as possible. The writer also pointed out that the plan was unnecessarily costly. As a result of that analysis the plan was not adopted and a re-study was made by the staff of the chief engineer of the Port Authority. In September, 1931, that staff produced a new plan eliminating these objectionable features as well as effecting an estimated saving in cost of construction and real estate of more than $10,000,000. This new plan was endorsed by all concerned, including the writer, and the tunnel was built according to it.

Although the through route from Long Island to New Jersey has been slow in emerging in complete form, it is gradually developing step by step. Another section of highway about three miles long, to be built from the easterly end of the present highway extending from the Queens plaza of the Queens Midtown Tunnel, is included in New York City's postwar program. It was recognized from the start that each link should form a part in a through express highway, and the links so far built or authorized fit into this scheme.

The writer is in accord with the plans of all sections so far built or authorized, with one exception. The New Jersey approach to the Hudson River tunnel, involving on the main route a corkscrew spiral with a continuous lift of 268 ft from under the river to the top of the Palisades, coupled with curves having radii of less than 300 ft for as much as one half of the complete circular loop, is not up to the standard of modern highway requirements, especially for commercial traffic.

A more detailed description of the various elements involved in the complete east-west route (of which the Queens Midtown Tunnel is a link) and their development is given in the writer's more complete paper filed in the Engineering Societies library at New York.

It is true, as Mr. Conover states, that the success of a vehicular tunnel depends largely on the plaza layouts together with the approaches.

The suggestion that the tunnel avenues for the Mid-Manhattan Underpass should correspond, for exit and entrance traffic flow, to the new avenues for the Queens Midtown Tunnel was given considerable study. The conclusion reached was that this arrangement would be expensive and impracticable. Although it would provide a slightly simpler traffic flow at some intersections, the disadvantages outweighed the advantages.

Automatic control of ventilation for a large tunnel, such as the Queens Midtown, would be an added expense with no saving or advantage gained, because an operator would have to be on duty at the remote control buttons at all times. Peaks of short duration would result in a great deal of fan-speed shifting if automatically controlled. These peaks can be "ironed out" with manual operation. The Oakland-Alameda Tunnel has (or had) automatic control. Automatic control is deemed advisable only on short and less important tunnels where such operation actually will save manpower on the operating payroll.

City fire apparatus has often passed through the Queens Midtown Tunnel, not on fire duty, but for access to the repair shop in Long Island City. No difficulty has been experienced on account of clearances. One lane only is necessary for the city's longest hook-and-ladder equipment, even on the smallest radius curve near the Manhattan portal.

Dr. Levy discusses, in considerable detail, the precautions taken during the construction of the Queens Midtown Tunnel to protect the men against compressed air illness, and also certain experiments which were undertaken, having in mind the development of better protection of the men from a medical point of view.

As one result of the investigations made on helium-oxygen mixtures, the installation and use of apparatus for the alleviation of ear block is specified as a requirement on the compressed air work on the Brooklyn-Battery Tunnel, on which work is now (1944) temporarily suspended on account of war conditions. If the results prove to be as satisfactory as anticipated, it may well be that the installation and use of apparatus to alleviate ear block should be a standard requirement for future compressed air tunnel work.

On the basis of past experience, and especially the experience on the Queens Midtown Tunnel, Dr. Levy suggests further study in regard to the present requirement of the New York State rules for the installation of a second tunnel bulkhead when pressures exceed 21 lb per sq in. The double bulkhead method of decompression did not show any advantage over the use of the single bulkhead on the Queens Midtown Tunnel in so far as the incidence of "bends" cases is concerned, and it seems appropriate to suggest that the present regulations might be modified advantageously to require that a second bulkhead be used as required by considerations of safety depending upon the physical conditions rather than upon any given air pressure in the tunnel heading. On the Manhattan side of the Queens Midtown Tunnel, where the distance between bulkheads was approximately 430 ft in one tunnel and 470 ft in the other, the second bulkheads were placed primarily because of the requirement of the regulations. As the headings entered full rock section in the rock reef approximately only 1,000 ft from the first bulkhead, serious consideration could have been given to the omission of the second bulkhead had it not been for the code requirement.

The question as to whether, in decompressing, the full amount of the fast initial drop of pressure as required by the present regulations may or may not be beneficial, seems to the writer to be a matter for further experimentation. It appears that Dr. Levy makes a pertinent statement in this connection when he writes, "In fact, it well may be that the fast initial drop of pressure in this method of decompression actually induces the beginning of the formation of the air bubbles that are the cause of compressed air illness."

Dr. Levy also suggests that further study be given to working one shift of six hours rather than two shifts of three hours in low pressures up to 18 lb per sq in. and possibly higher. Although this would be an interesting experiment, there may be some practical objections to it in actual practice. It may be questionable whether a man working six hours continuously, regardless of whether or not he is working in compressed air, would produce a satisfactory six hours' work. There is a present-day tendency in certain industries to give employees short rest periods at various intervals during the day to offset fatigue. It may be questioned whether a man working six hours continuously would be operating at full efficiency during the latter part of the period, and this condition might be hazardous in tunnel work where alertness and efficiency are required at all times for reasons of safety.

Professor Legget has raised several pertinent questions: The ratchet wrenches used for bolt tightening were standard equipment. Fixed maximum-torque wrenches have been considered for use on the Brooklyn-Battery Tunnel, where the minimum bolt stress specified is 30,000 lb per sq in. It was found that there were no maximum-torque wrenches on the market of sufficient capacity for this specification and one was ordered to be constructed specially. It was impossible to get this wrench on account of war conditions. If the trial had proved successful it was contemplated that inspectors of the Tunnel Authority would be provided with torque wrenches and would spot-check the bolts for tightness. It was considered impracticable to use torque wrenches for the actual tightening.

In experimenting to determine the torque necessary to produce a given stress, it was observed that there was quite a range in the frictional behavior of different combinations of bolt, nut, and washer. This would be expected, especially since the bolts are forged and the threads rolled. In this process threads are sometimes burred in packaging and handling, and the nuts and washers have a relatively rough finish.

When conditions permit resumption of construction work on the Brooklyn-Battery Tunnel, the investigation of the use of torque wrenches to test bolts will be continued.

The drainage system considered for the Manhattan plaza of the Queens Midtown Tunnel involved excavating to expose the rock surface over the entire plaza area, the construction of a fairly complicated system of drainage pipes, galleries, sumps and pump chambers, and backfilling to subgrade of the invert slab with gravel. The heavy slab was estimated to cost little more than the drained plaza, which involved more excavation, the cost of gravel backfill, and higher unit costs of concrete than the massive slab, besides the drainage system itself. As the cost was practically the same as that for the heavy slab design and there was an unusual ground-water condition (ground water being as high as 19 ft above mean high water at one point) the heavy invert slab was adopted as involving no operation and maintenance costs.

Clay for blanket purposes is chosen because it is a dense, erosion-resistant material that can be obtained economically in the large quantities required. This generally results in a clay being obtained from a near-by source. The clay used for blanket purposes on the Queens Midtown Tunnel had a weight of 115 lb per cu ft and was dredged from Newark Bay, a previously used source of clay for blanket purposes.

The volcanic clay referred to is a form of bentonite described as a type of clay originating from volcanic eruptions and consisting chiefly of mineral montmorillonite, a hydrous silicate of aluminum. It is found almost exclusively in the Black Hills region of the United States (South Dakota). It possesses in high degree the qualities of absorption and swelling, and will re-swell after drying for an indefinite number of cycles. Its swelling properties are used in retarding or stopping the flow of water, and in the tunnel it was used as an aid in the attempt to reduce the escape of compressed air through porous material.

Mr. Brodie's analysis of the tunnel ring, together with the resulting design for the cast-iron lining of the Holland Tunnel which he describes, is still representative of fundamental principles in this art. Very important is his statement, "Subaqueous shield-tunnel practice recognizes the uncertainty of absolute values of external loading, especially at critical times during construction." There is sometimes a tendency for theorists not familiar with practical shield tunneling to lose sight of this principle.

The lining section actually used for the Holland Tunnel is not to be confused with Fig. 18, "Cast-Iron Details, Heavy, 29-Ft Sections, Holland Tunnel."

The outside radius of the adopted section was 14 ft 9 in. and in some cases 15 ft 2 in.; the web thickness was 1⅝ in. increasing to 2¾ in. at the flanges. Mr. Brodie made it clear in his discussion that the lining shown in Fig. 18 formed the basis of the design and analysis but that the modified sections, with the foregoing dimensions, were actually used. The figure alone, however, might be misleading.

Referring to feature (8) of Mr. Brodie's discussion, "effect of transverse tie rods," it may be pointed out that the firm character of the material surrounding the Queens Midtown Tunnel tubes made such permanent tie rods unnecessary, except for the short stretches under the Manhattan bulkhead and at the midriver sump, as stated in the paper.

In his letter of September 27, 1943, to the writer, written only eight days before his death, Mr. Brodie requested that in this discussion mention be made of those who assisted in his work on the design of the cast-iron lining for the Holland Tunnel, as follows: Henry G. Babcock, Assoc. M. Am. Soc. C. E., James H. Dugan, M. Am. Soc. C. E., Jacob Mechanic, Assoc. M. Am. Soc. C. E., and Morris Cohen.

Some of the statements made by Mr. Eremin call for further comments, and a few of them will be discussed briefly. The protective blanket acts primarily as a counterweight against rupture of the river bed due to the unbalanced air pressure in the upper part of the face of the tunnel heading. If the face of the tunnel is in porous material, the imperviousness of the blanket does not accomplish much in preventing the escape of air from the tunnel. As escaping air from the tunnel does find fissures and other such avenues of escape through the blanket, the blanket is eroded to an extent sometimes requiring constant replacement under these circumstances. If the blanket were entirely impervious, air would continue to escape from a tunnel heading in porous material and find its way out around the edges of the blanket. A dense and erosion-resistant material is indicated for blanket purposes.

If the tunnel heading is in impervious material, the required air pressure is generally less than theoretical hydrostatic head and there is no unbalanced air pressure tending to blow out the river bed. Under these conditions a blanket would not be necessary, even though the natural cover over the tunnel were not great. For this reason blankets and loss of air in shield tunneling are generally associated. To the best of the writer's information, the blanket used in the East Boston Tunnel was used to build up low spots in the river bed, thus providing a uniform total thickness of cover of only 15 ft over the tunnel. Altogether only 7,200 cu yd of clay were used for the blanket, most of it deposited at pierhead lines to consolidate the mud and increase cover from 9 or 10 ft to 15 ft, as a precaution against material running into the heading. There was no danger of a blowout as the material penetrated by the tunnel was largely impervious clay, plastic to stiff in consistency, and air pressures used were generally below theoretical hydrostatic head.

The use of grout to reduce air leakage at the face, and its use to fill the annular space around the tunnel lining left by the tail of the shield should not be confused. Its latter use is standard practice and has little, if any, effect on shield progress, whereas the effectiveness of grouting the face, which is done only under unusual circumstances, might have some effect on shield progress.

Mr. Eremin should not include the Lincoln Tunnel with his examples of structural steel-lined shield-driven tunnels. The shield-driven sections of the Lincoln Tunnel were lined with cast iron; the approach tunnels in full section of rock, built without the use of shields, were lined with steel, as were the Manhattan approach tunnels of the Queens Midtown Tunnel.

The writer had no intention of inferring that further study is not necessary in the planning and designing of tunnels for highway traffic. On the contrary, he is convinced that each such project requires a large amount of study and planning to meet the conditions peculiar to each location. The writer had in mind, however, that only twenty-five years ago (1919) long tunnels, designed for the exclusive use of motor-driven vehicles, were considered in the nature of an experiment and were looked upon with skepticism, not only by the general public but also by some engineers. During the intervening period extensive research work has been conducted on some of the important phases relating to this kind of project and much has been learned through operating experience of the several such tunnels which have been built and are now in operation.

When the Holland Tunnel was being planned, an extensive program of research was conducted, involving the expenditure by the Tunnel Commissions of more than $100,000 and by the cooperating agency, the U. S. Bureau of Mines, of a considerable amount. This research work was intensively promoted over a period of two years and since has been continued intermittently to provide supplementary information on related phases of the same problem. The uncertainty and apprehension with regard to this phase of vehicular tunnel design were effectively overcome by the striking success of the ventilation system developed as a result of that research work.

Another illustration of a question that was then considered uncertain by some engineers was the suitability of cast iron as the primary lining for such a large tunnel in a material like the Hudson River silt. The design of the lining for the Holland Tunnel, which involved a much larger diameter in Hudson River silt than had before been constructed, was quite properly the subject of open technical discussion. In one paper[27] the opinion was expressed that "In soils with a low angle of repose, for any specific case presented, there is a limiting inside diameter (which may be determined for that case) beyond which the primary lining, whether of cast iron or of concrete blocks, cannot be designed to stand without internal bracing." At considerable variance with the design and analyses of the Holland Tunnel engineers, and predicated on the line of reasoning on which the foregoing conclusion was based, it was determined in that paper that the inside diameter of a cast-iron lined tunnel not subject to non-elastic deformation in Hudson River silt would be limited to 26.2 ft with flanges more than 5 ft deep and an outside diameter of more than 36 ft, the lining segments at this diameter being unwieldy in size, number, and weight. However, with faith in their own determinations, the Holland Tunnel engineers designed and successfully constructed in Hudson River silt a cast-iron lining of

[27] "Notes on Tunnel Lining for Soft Ground," by S. Johannesson and B. H. M. Hewett, *Transactions* Am. Soc. C. E., Vol. LXXXIII (1919–1920), pp. 1845 and 1855.

29 ft 6 in. outside diameter and 14-in. flanges or 27 ft 2 in. inside diameter, the general features and details of which have subsequently set the pattern for cast-iron lining of 31 ft outside diameter in both the Hudson and East rivers. A synopsis of this design and analysis is mentioned in Mr. Brodie's discussion.

One more illustration of the extensive research work which was necessary heretofore is that referred to in the comments on Mr. Thoresen's discussion regarding the development of a suitable wall tile for this type of tunnel.

The writer is indebted to Mr. Tuttle for a concise statement of the historical background of the Queens Midtown Tunnel.

The adequate highway approaches to the tunnel, both in Manhattan and Queens, to which Mr. Tuttle refers, have to a large extent yet to be provided. That these approaches could not have been included, as part of the tunnel project on a self-liquidating and self-supporting basis, is self-evident. It is generally the practice of New York City to make its toll river crossings a real part of its free highway system. In the case of the Queens Midtown Tunnel this practice has met with serious delays which the writer hopes will soon be overcome.

A SYMMETRICALLY LOADED BASE SLAB ON AN ELASTIC FOUNDATION

By Stanley U. Benscoter,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Robert O. Jameson, L. J. Mensch, Alfred L. Parmé, A. A. Eremin, A. E. Cummings, Harris Epstein and James R. Ayers, Jr., and Stanley U. Benscoter.

Synopsis

In the design of a base slab it is common practice to assume the reaction distribution and compute bending moments by statics, or by elastic theory if the slab is part of an indeterminate frame. In the latter type of case, fixed-end moments and stiffness values are computed as for an ordinary beam or slab with fixed load distribution. The object of this paper is to develop a method of analysis which takes account of the effect of the rigidity of the foundation upon the reaction distribution. The base slab extends between two vertical walls to which it is rigidly connected. The slab is considered to be acted upon symmetrically by thrust, shear, and moment from the vertical walls. Formulas and graphs for stiffness and fixed-end moment values are presented so that moments can be obtained by moment distribution.

Notation

The letter symbols introduced in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

Reaction-Displacement Relationship

A reasonable shape of the displacement and reaction diagrams for a base slab is obtained if the assumption is made that the upward reaction, w, at each point is proportional to the downward displacement, z, at that point. This assumption is expressed by

$$w = -k\,z \quad\text{(1)}$$

in which k is the foundation modulus. This simple manner of foundation behavior is assumed for convenience. The relationship is exact for a slab floating in a liquid and may be called the basis of the "floating slab" theory.

Note.—Published in May, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] The Engineer Board, Bridge Section, Fort Belvoir, Va.

If the foundation is elastic, isotropic, and homogeneous a correct solution could be obtained by replacing the constant k by the reciprocal of an influence function. At present, any assumed relationship between displacements and reactions for a slab resting on a soil subgrade must be regarded as an approximation.

The constant k may be obtained experimentally from a plate-loading test. A stress-displacement curve is plotted and the average slope of the curve in the working range is determined. This slope is the foundation modulus. It is essential that the loaded plate have at least 5 sq ft of area. Values of k for soil commonly range from 100 to 200 lb per cu in., although greater or less values are not unusual. The lower value of 100 lb per cu in. is recommended for design purposes when the results of plate-loading tests are not available. For more rigid foundations, such as shale or limestone, an estimate of a reasonable value of k for design is given (in pound-inch units) by:

$$k = \frac{E'}{100} \qquad (2)$$

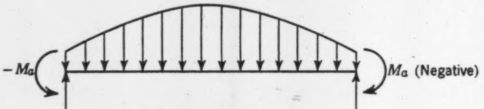
in which E' is the modulus of elasticity. The application of floating slab theory to such rigid foundations must be regarded as a temporary method of solution to be used only until a more exact method becomes available.

SLOPE-DEFLECTION EQUATION FOR A SYMMETRICAL BEAM

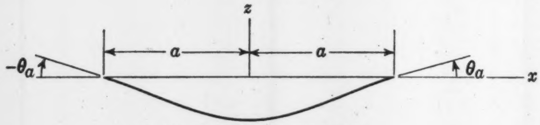
It is desirable to consider first the slope-deflection equation for a prismatic beam with symmetrical loading and symmetrical end moments, as shown in Fig. 1. The equation takes the following simplified form, $M_a = M'_a + \frac{E\,I}{a}\,\theta_a$; or

$$M_a = M'_a + \phi_0\,\theta_a \qquad (3)$$

in which M'_a is the value of M_a when the ends of the beam are fixed; E is



(a) FORCE DIAGRAM



(b) DISPLACEMENT DIAGRAM

FIG. 1.—SYMMETRICALLY LOADED PRISMATIC BEAM

the modulus of elasticity for an isolated beam or a modified modulus of elasticity $\frac{E'}{1 - \mu^2}$ if the beam is a slice of a slab; I is the moment of inertia of the beam or the moment of inertia of the slab per unit of width; ϕ_0 is the stiffness of the beam; and θ_a is the end rotation angle (or end slope). The signs of the terms in this equation are correct for the usual slope-deflection sign convention at either end of the beam. In a bending-moment sign convention the equations are correct only at the right end of the beam. Throughout this paper a bending-moment sign convention will be used, and the signs that appear in the equations will be such that the equations are applicable to the right half of the beam.

The coefficient ϕ_0 in Eq. 3 is a modified beam stiffness for the case of symmetrical end moments and may be obtained readily by multiplying the standard stiffness[2] value $\frac{4\,E\,I}{L}$ by the applicable end-rotation constant[3] $\frac{1}{2}$. It is apparent from Eq. 3 that ϕ_0 is the change in the end moment M_a caused by a unit change in θ_a, or a unit end rotation. Eq. 3 gives the end moment M_a as a linear function of the end slope θ_a. The convenience of the moment distribution process of analysis arises from the fact that M_a and θ_a are related linearly. It will be shown that this same linear relationship holds true for an elastic slab on an elastic foundation. The formulas for fixed-end moment and stiffness contain the foundation modulus as well as the flexural properties of the slab.

It is possible also to write the moment at any point of the beam in the same form as Eq. 3; thus:

$$M(x) = M'(x) + \phi_0\,\theta_a \qquad (4)$$

The fixed-end moment $M'(x)$ is a function of x. The stiffness ϕ_0 is a constant which, as before, is the change in the moment $M(x)$ caused by a unit end rotation. In the case of a beam on an elastic foundation, the change in moment at a point x, caused by a unit end rotation, is not a constant but a function of x. Hence, the constant ϕ_0 must be replaced by a function of x.

BEAM FUNCTIONS

The base slab under consideration is regarded as a plane strain problem and a slice of the slab one unit thick is considered in the analysis. This slice may be treated as a beam.

The beam functions to be determined are the displacement, slope, moment, and shear, each of which may be written in a form analogous to Eq. 4:

$$z(x) = z'(x) + \phi_1(x)\,\theta_a \qquad (5a)$$

$$\theta(x) = \theta'(x) + \phi_2(x)\,\theta_a \qquad (5b)$$

$$M(x) = M'(x) + \phi_3(x)\,\theta_a \qquad (5c)$$

and

$$V(x) = V'(x) + \phi_4(x)\,\theta_a \qquad (5d)$$

Eq. 5c is obtained from Eq. 4 by replacing ϕ_0 by $\phi_3(x)$. The function $\phi_3(x)$ contains ϕ_0 as a factor and may be written in the following forms,

$$\phi_3(x) = \phi_0\,S(x) = \frac{E\,I}{a}\,S(x) \qquad (6)$$

---

[2] "Continuous Frames of Reinforced Concrete," by H. Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 83.

[3] *Ibid.*, p. 119.

The function $S(x)$ remains to be determined. At the end of the beam, where $x = a$, the function ϕ_3 becomes,

$$\phi_3(a) = S_a \frac{E\,I}{a} \dots\dots\dots\dots (7)$$

It is the stiffness value $\phi_3(a)$ that is needed to distribute moments by the method of moment distribution. The fixed-end moment at the end of the beam M'_a is also needed.

In actual design practice it is not necessary to compute the end rotation angle θ_a. The moment distribution process gives the final end moment M_a without a computation of θ_a. If the change in end moment from M'_a to M_a is called ΔM_a, the beam functions can be expressed in terms of ΔM_a instead of θ_a. The moment at the end of the beam, from Eq. 5*c*, is:

$$M_a = M'_a + \phi_3(a)\,\theta_a \dots\dots\dots\dots (8)$$

Consequently,

$$\Delta M_a = M_a - M'_a = \phi_3(a)\,\theta_a \dots\dots\dots\dots (9a)$$

or,

$$\theta_a = \frac{\Delta M_a}{\phi_3(a)} \dots\dots\dots\dots (9b)$$

Substitution of this formula for θ_a into Eqs. 5 gives the beam functions in the following forms:

$$z(x) = z'(x) + \psi_1(x)\,\Delta M_a \dots\dots\dots\dots (10a)$$

$$\theta(x) = \theta'(x) + \psi_2(x)\,\Delta M_a \dots\dots\dots\dots (10b)$$

$$M(x) = M'(x) + \psi_3(x)\,\Delta M_a \dots\dots\dots\dots (10c)$$

$$V(x) = V'(x) + \psi_4(x)\,\Delta M_a \dots\dots\dots\dots (10d)$$

in which

$$\psi_i(x) = \frac{\phi_i(x)}{\phi_3(a)}; \qquad i = 1, 2, 3, 4 \dots\dots\dots\dots (11)$$

The fixed-end functions and the ϕ-functions or ψ-functions must be determined by solving the differential equation which governs the displacement of an elastic beam.

SOLUTION OF THE DISPLACEMENT EQUATION

The elastic base slab in Fig. 2 is resting on an elastic foundation. The forces and moments that act on the beam are shown and also the displacements caused by the acting forces. The reaction and displacement diagrams have the same shape and are proportional in agreement with Eq. 1. The displacement of a point on the elastic curve of a prismatic beam is governed by the following equation,

$$\frac{d^4z}{dx^4} = \frac{w}{E\,I} \dots\dots\dots\dots (12)$$

The load w on the beam in the present case is the reaction that has been expressed in terms of z by Eq. 1. Substitution of Eq. 1 into Eq. 12 gives

$$\frac{d^4z}{dx^4} + \frac{k}{E\,I}\,z = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

The form of the solution of this equation can be simplified by the following substitution,

$$\frac{k}{E\,I} = \frac{4}{\lambda^4} \quad\ldots\ldots (14)$$

so that Eq. 13 becomes,

$$\frac{d^4z}{dx^4} + \frac{4}{\lambda^4}\,z = 0 \quad\ldots (15)$$

The fundamental length λ may be obtained by solving Eq. 14:

$$\lambda = \sqrt[4]{\frac{4\,E\,I}{k}} \quad\ldots\ldots (16)$$

In Eq. 16 the numerator of the fraction beneath the radical is the standard stiffness of a unit length of the beam, whereas the denominator is the stiffness of the foundation.

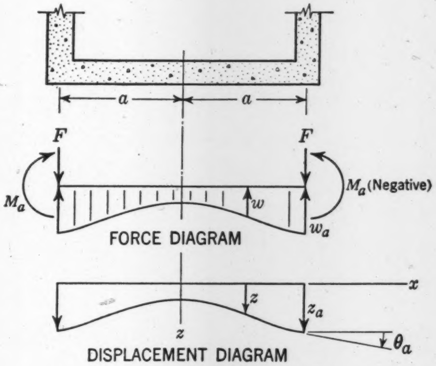


FIG. 2.—BASE SLAB WITH FORCE AND DISPLACEMENT DIAGRAMS

The solution of Eq. 15 may be written in the following form,

$$z = A \sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} + B\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda} + C\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + D\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda} \quad\ldots (17)$$

in which A, B, C, and D are arbitrary integration constants. This solution contains four constants since it is the solution of a fourth-order differential equation. It is necessary to evaluate the constants of integration in such a manner that the desired boundary, or end, conditions of the beam are satisfied.

Since the displacements are symmetrical about the z-axis, the coefficients of the antisymmetrical terms may be set equal to zero.

$$C = D = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

Since it is desired to obtain the beam functions in terms of θ_a the first derivative of z at the end of the beam must be set equal to θ_a. The end shear is $-F$. These two end conditions give the following equations for determining A and B.

$$\left[\frac{dz}{dx}\right]_a = \theta_a \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19a)$$

and

$$\left[\frac{d^3z}{dx^3}\right]_a = -\frac{F}{E\,I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19b)$$

If the derivatives of Eq. 17 are substituted into Eqs. 19, two linear equations in A and B are obtained, which can be solved simultaneously to obtain,

$$A = \frac{v\,\lambda^3\,F}{2\,E\,I} + u\,\lambda\,\theta_a \qquad (20a)$$

and

$$B = \frac{u\,\lambda^3\,F}{2\,E\,I} - v\,\lambda\,\theta_a \qquad (20b)$$

in which

$$u = \frac{\sin\alpha\cosh\alpha + \cos\alpha\sinh\alpha}{\cosh 2\,\alpha - \cos 2\,\alpha} \qquad (21a)$$

and

$$v = \frac{\sin\alpha\cosh\alpha - \cos\alpha\sinh\alpha}{\cosh 2\,\alpha - \cos 2\,\alpha} \qquad (21b)$$

The functions u and v have been introduced for convenience. They are represented graphically in Fig. 3. If the formulas for A, B, C, and D are substituted into Eq. 17, the displacement z is obtained in the form of Eq. 5a; thus,

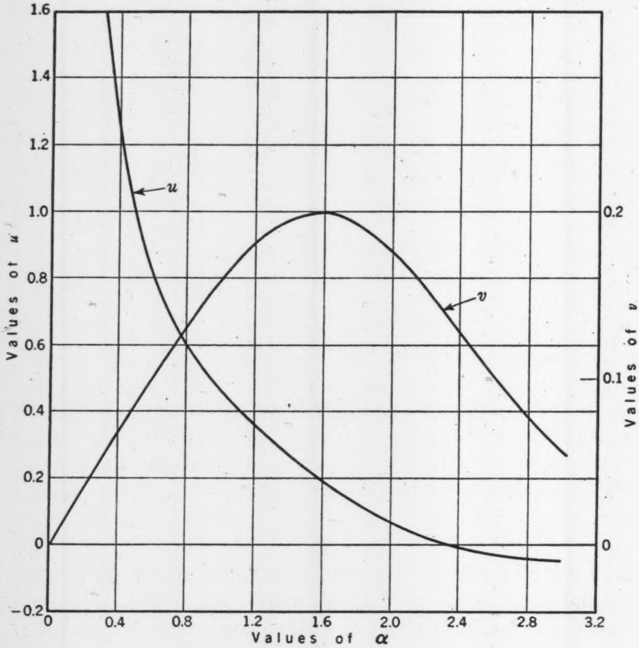

FIG. 3.—CONVENIENT FUNCTIONS OF α (SEE EQS. 21)

$$z = \frac{F\,\lambda^3}{2\,E\,I}\left(v\sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} + u\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) + \theta_a\,\lambda\left(u\sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} - v\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \qquad (22)$$

The first term is the fixed-end function and the second term is the product of θ_a and the end-rotation, or ϕ, function.

FIXED-END FUNCTIONS

The slope, moment, and shear of an elastic, prismatic beam may be expressed in terms of the derivatives of z by

$$\theta = \frac{dz}{dx} \qquad (23a)$$

$$M = E\,I\,\frac{d^2z}{dx^2} \qquad (23b)$$

and

$$V = E\,I\,\frac{d^3z}{dx^3} \qquad (23c)$$

If the formula for z obtained from Eq. 22 by setting $\theta_a = 0$ is differentiated and substituted into Eqs. 23, the following fixed-end functions are obtained.

$$z'(x) = \frac{F\,\lambda^3}{2\,E\,I}\left(v \sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} + u \cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \qquad (24a)$$

$$\theta'(x) = \frac{F\,\lambda^2}{2\,E\,I}\left[(v-u)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u+v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right] \qquad (24b)$$

$$M'(x) = -F\,\lambda\left(u \sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} - v\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \qquad (24c)$$

and

$$V'(x) = -F\left[(u+v)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u-v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right] \qquad (24d)$$

END-ROTATION FUNCTIONS

The effect of a unit end rotation on deflections can be obtained from Eq. 22 by setting $F = 0$ and $\theta_a = 1$. The deflection formula thus obtained can be differentiated and substituted into Eqs. 23 to obtain the remaining end-rotation functions. These end-rotation functions are,

$$\phi_1(x) = \lambda\left(u \sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} - v\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \qquad (25a)$$

$$\phi_2(x) = (u+v)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u-v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda} \qquad (25b)$$

$$\phi_3(x) = \frac{2\,E\,I}{\lambda}\left(v \sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} + u\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \qquad (25c)$$

and

$$\phi_4(x) = \frac{2\,E\,I}{\lambda^2}\left[(v-u)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u+v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right] \qquad (25d)$$

It is interesting to note that the functions of x, which are contained in the parentheses or brackets of the fixed-end functions, appear again in the end-rotation functions but in different order. The fixed-end functions and the end-rotation functions now can be substituted into Eqs. 5 to obtain a complete statement of the beam functions.

DESIGN FORMULAS

From the formulas that have been derived the numerical values of the beam functions can be computed at any point x providing either ΔM_a, or θ_a, has been determined. The determination of ΔM_a rather than θ_a offers the preferable method of solution since the designer is vitally concerned with end-moment changes but has little interest in numerical values of end rotations. Whenever possible, a practicing engineer instinctively prefers to deal entirely with bending moment values in a structure analysis. If the end moment M_a can be determined by statics, then ΔM_a can be computed from its definition as given in Eq. 9*a*. An example of this type of structure is an open water channel constructed as a monolithic frame, such as a spillway channel or a stilling basin.
